ABSTRACT

In the present study, we report a case of successful endotracheal intubation using Airtraq™ Laryngoscope (AQL) in a morbidly obese patient. A 35-year-old woman, morbidly obese (weight, 105 kg; height, 160 cm; BMI, 41 kg/m^2), known hypertensive and diabetic, was admitted in the operating room for total abdominal hysterectomy under general anesthesia. The preoperative airway assessment anticipated both difficult bag-mask ventilation and intubation. Tracheal intubation using AQL was attempted after induction with propofol and relaxation with succinylcholine. Successful tracheal intubation was accomplished within 12 seconds of insertion of AQL into the oral cavity. The minimal hemodynamic response during this maneuver was advantageous in our patient.

Key words: *Airtraq™ optical laryngoscope, difficult intubation, morbidly obese*

INTRODUCTION

Morbidly obese patients (body mass index [BMI] > 40) (BMI = weight in kilogram/[height in centimeter]^2) present a challenge to the anesthesiologist in terms of securing the airway. Predictors of difficult laryngoscopy and intubation in these patients include fat face and cheeks, large breasts in females, limited range of motion of head, neck and jaw, small mouth and a large tongue, excessive palatal and pharyngeal tissue, short thick neck (large circumference), high Mallampati scores (III or IV) and more rapid oxygen (O_2) desaturation.[1] Associated comorbidities such as hypertension and diabetes add to the already difficult situation in terms of exaggerated hemodynamic response to laryngoscopy and intubation.

The Airtraq™ (Prodol Meditec S.A., Vizcaya, Spain) optical laryngoscope is a useful tracheal intubation device that can be used in patients with potential difficult airway, as in our case. It shortens the duration for tracheal intubation, and thus prevents reduction in arterial O_2 saturation.[2] Because of less forceful blade elevation, maneuvering is gentle with minimal hemodynamic alterations,[3] adding to the advantage in hypertensive patients.

We report a case of successful and rapid (12 seconds) endotracheal intubation in a morbidly obese patient using AQL.

CASE REPORT

A 35-year-old woman, with 105 kg weight and 160 cm height (BMI, 41 kg/m^2), having dysfunctional uterine bleeding unresponsive to medical management, was admitted in the operating room for total abdominal hysterectomy under general anesthesia. She had well-controlled hypertension, diabetes mellitus type II, history of snoring and symptoms of gastroesophageal reflux. No history of obstructive sleep apnoea was detected. The preoperative airway assessment showed Mallampati class IV, interincisor gap of 3 cm, thyromental distance of 5.5 cm, and neck circumference of 55 cm. Head extension and cervical flexion were markedly limited. Patient was anemic with moderate pallor, resting pulse rate of 100/min, blood pressure of 150/94 mmHg, and fasting blood glucose of 116 mg/dl on the day of surgery, while other preoperative laboratory investigations were within normal limits. Informed consent was taken from the patient. Difficult airway cart was prepared, including the instruments of

cricothyrotomy and tracheostomy, as difficulty in mask ventilation and intubation was anticipated. Endotracheal tube of 7.0 mm ID was lubricated and then passed through the side channel of Airtraq™ laryngoscope. Patient was put in supine position, her head supported with a soft pillow put under the head, and premedicated with Ondansetron 8 mg, Tramadol 200 mg and Midazolam 2 mg intravenously (i.v.). After preoxygenation with 100% O_2 for 3 minutes, induction with propofol 200 mg i.v. and relaxation with succinylcholine150 mg i.v., endotracheal intubation was attempted with Airtraq™ laryngoscope. A full view of centered glottis could be obtained after elevation of the epiglottis and endotracheal tube could be passed through the vocal cords easily. Time taken from insertion of Airtraq™ into the oral cavity to successful endotracheal intubation was 12 seconds. Endotracheal intubation was confirmed by capnography and auscultation of the chest. During this time, patient's pulse rate, blood pressure and ECG were within normal limits. No desaturation and mucosal bleeding occurred during intubation. Endotracheal tube was secured in place and the surgeons were asked to proceed with the surgery. General anesthesia was maintained with propofol infusion and mixture of O_2 and nitrous oxide and neuromuscular blockade using vecuronium. The procedure lasted 2 hours; residual neuromuscular paralysis was reversed with neostigmine and glycopyrrolate, after which she was successfully extubated with an uneventful recovery. Patient maintained saturation in head-up position in the post-operative period on O_2 through mask. The patient exhibited only mild symptoms of sore throat that improved within 2 days without any intervention; otherwise, the post-operative period was uneventful. No hoarseness and other airway complications were noted.

DISCUSSION

Obesity can be a potential cause of complications after induction of anesthesia resulting from rapid desaturation,[4] limited mobility of atlanto-occipital and temporomandibular joints, narrowed upper airway, shortened distance between the mandibular and sternal fat pads, and delayed gastric emptying with gastro-esophageal reflux leading to pulmonary aspiration.[5]

AQL is a new device providing direct view of the glottis, with minimal maneuvering of patient for optimal positioning. There are reports demonstrating successful intubation using AQL in normal airways,[6] simulated difficult airways[7] and in a clinically difficult airway.[8,9] It has been used electively[10] as well as a rescue device[11] after failed attempt with conventional laryngoscopy.

Our patient, a morbidly obese woman (BMI, 41 kg/m^2) was successfully intubated with AQL in 12 seconds. Ndoko *et al.* (2008) also demonstrated that AQL shortened the duration of tracheal intubation and prevented reduction in O_2 saturation.

Hemodynamic changes (heart rate, blood pressure) were minimal during intubation using AQL. Similar findings have also been shown by Maharaj *et al.* (2007) and Ndoko *et al.* (2008).

MRSA
Screening

ABSTRACT

Objective: This study was undertaken to determine the carriage of MRSA strains due to nasotracheal intubation into the lower respiratory tract where they can be a potential source of infection leading to high morbidity and mortality. **Materials:** Study was done on 100 patients (50 intubated nasally and 50 intubated orally). Swabs were taken from the anterior nares, throat and tip of the endotracheal tube (ETT tip), cultured on conventional media and sensitivity was determined.**Results:** In study group 1, nasal swabs showed growth of MRSA in 21 (42%) patients and out of these 16 (76%) patients showed growth of MRSA strains from ETT tip. MRSA was not detected from ETT tip in any of the patients in study group 2. Screening for MRSA should be done before intubation by nasal route.

1. Introduction

Nasotracheal intubation is a procedure commonly required for patients undergoing maxillofacial and dental surgeries [1]. There are well documented complications of this procedure like nasal sinusitis, nasal septal and parapharyngeal abscesses [2,3]. Nosocomial pneumonia and septicemia are more frequent in patients with nasotracheal intubation than those intubated orotracheally [4,5].

MRSA is the term used for Methicillin Resistant Stapyhlococcus Aureus which are relatively difficult to treat pathogens. If resistant to Methicillin, these strains are also resistant to Flucloxacillin and all β-lactam antibiotics. Upto 40% of the normal population carry *S.aureus* in the anterior nares for periods ranging from a few weeks to many years and this carriage rate is often increased in hospitalized patients. The increasing incidence of MRSA has been associated with hospital outbreaks leading to considerable morbidity and mortality[6]. Patients with compromised immune systems are at a greater risk of symptomatic secondary infection. MRSA can be detected by swabbing the nostrils of patients and isolating the bacteria found inside. At risk populations include : people with weak immune system (people with HIV/AIDS, transplant recipients, severe asthmatics etc.), diabetics, i.v drug users, use of quinolone antibiotics, young children, elderly, college students living in dormitories and people who spend time in confined spaces.

The present study was done to determine intubation related carriage of bacteria, especially MRSA into trachea mainly on nasotracheal intubation.

2. Material and methods

The study was done in departments of Anesthesiology and Microbiology of J.N. Medical College and Hospital. Hundred patients were included in the study.

Study group 1 comprised of 50 patients who were intubated by nasotracheal route due to conditions that led to difficult mouth opening or requiring more space for the surgical procedure. Study group 2 comprised of 50 patients who were intubated by oral route. Detailed history regarding prior use of antimicrobial agents like β-lactamase inhibitor combination, Fluoroquinolones, Macrolides, Cephalosporins and Vancomycin, steroid therapy, bronchoscopy, diabetes

and dialysis was recorded from all patients. History of hospitalization was also taken.

2.1. Anaesthetic technique

Informed consent was taken from all the patients. Patients were intubated by nasal route using standard protocol [7]. Difficult airway cart including the instruments of surgical airway techniques (cricothyrotomy, tracheostomy) were kept ready. Nasal patency was checked on both sides and the right naris was selected for Nasotracheal intubation as the bevel of most of the ETT will face the flat nasal septum minimizing damage to the turbinates. We instilled cotton-tip pledgets soaked with 2 % Lignocaine with 1:200000 epinephrine in both the nasal passages 10-15 minutes prior to intubation. Premedication was done with Inj. Ondansetron 0.1 mg/kg intravenous (IV), Inj. Tramadol 2 mg/kg IV and Inj. Midazolam 0.04mg/kg IV. Patients were pre-oxygenated with 100% Oxygen for 3 minutes and induced with Inj. Thiopentone 3-5 mg/kg IV and relaxed with Inj. Succinylcholine 1-1.5 mg/kg IV. Cuffed endotracheal tube PVC type lubricated with sterile cotton soaked Lignocaine jelly was introduced to the half of its length into right nasal passage. The blade of MacIntosh laryngoscope was introduced into the mouth from the right side and advanced upto the faucial pillars. Next the tongue was swept and the blade was moved further to position its tip in the vallecula for lifting the epiglottis. Under visual guidance, Nasotracheal intubation was done pushing the endotracheal tube through the abducted vocal cords with the help of Magill's forceps. Correct placement of the tube was confirmed by capnography and auscultation. Patient was maintained on Oxygen and Nitrous Oxide mixture, Inj. Propofol and Inj. Vecuronium. Vital parameters including the pulse rate, blood pressure and pulse-oximetry were monitored in all patients. After the surgical process, the patients were successfully extubated. Sterility was fully maintained throughout the procedure.

Three swabs were taken from each patient - nasal, pharyngeal and swab from the tip of tube (ETT tip). Throat and nasal swabs were taken prior to intubation and swab from tube tip after procedure was completed and sent to microbiology laboratory in Brain-Heart infusion broth. All three swabs were inoculated on blood agar and McConkey's agar at 37 degree Celsius overnight. The isolates were identified by their characteristic morphological features and by battery of standard biochemical reactions for identification of gram-positive and gram-negative cocci.

MRSA detection was done using Oxacillin disc susceptibility testing using CSLI guidelines (8). A bacterial suspension adjusted to 0.5 MacFarland was inoculated onto Muller-Hinton agar. A filter paper disc containing Oxacillin (Hi-media, India) was placed on the inoculated agar and plates were incubated overnight. The diameter of zone of inhibition was measured and standard criteria for interpretation of results were employed (8). Antimicrobial susceptibility pattern of isolates was determined using Kirby-bauer disc diffusion technique.

3. Results

A total of 100 patients included in the study belonged to different age groups. Thirty-three patients (21 in study group 1 and 12 in study group 2) had shown positive culture for MRSA from nasal swab specimen.

Table 1.
Showing distribution of patients positive for MRSA growth on nasal swab according to rate of isolation from ETT tip after different routes of intubation

Intubation Procedure	MRSA carriage into trachea		Total
	Yes	No	
Nasal intubation	16 (76%)	5 (24%)	21
Oral intubation	0 (0%)	12 (100%)	12
Total	16	17	33

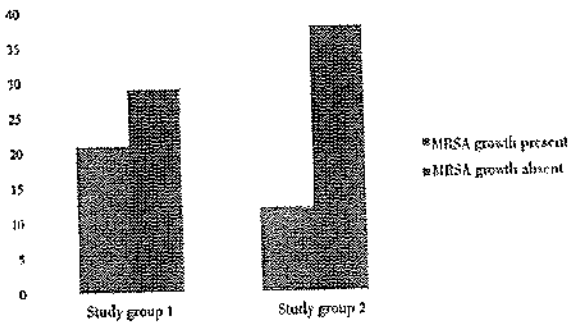

Figure 1. Distribution of MRSA strain in nasal swab specimens

In study group 1 (comprising of 50 patients intubated nasotracheally), general nasal commensal microflora was present on culture examination of their nasal swab specimens. Twenty-one patients (42%) showed colonization with MRSA. Throat swabs of these patients had commensal growth while Streptococcus pyogenes was isolated from throat of 1 patient. On culture examination from ETT tip, MRSA was detected in 16 (76%) patients whose nasal swab culture also showed MRSA. Streptococci were detected in 8 patients.

In study group 2 (comprising 50 patients intubated orotracheally), the ETT tip showed growth of staphylococcus sp and streptococcus sp in 5 patients. Nasal swabs of 12 patients in this group had shown MRSA growth, while none of them had shown MRSA growth on ETT tip culture.

4. Discussion

The results of this study indicate that bacteria are being carried into the trachea more frequently by intubation via nasal route than oral route. Satoshi Takahashi et al 2003 (9) reported carriage of bacteria from nasal cavity into trachea

because of nasal intubation. Other investigators reported that nasal cannulation for endotracheal and gastric intubation is a major risk factor for Nosocomial infection [9-11]

In this study, the nasal carriage rate of MRSA was found to be 33%. Dupeyron et al [12] reported nasal carriage rate of MRSA of 16.3% while Corbella et al (13,14) and Satoshi Takahashi et al [9] reported nasal carriage rate of 22.1% and 13.2% respectively. The high rate of nasal carriage of MRSA found in our study may be due to random selection of patients.

In this study, we found that the transfer rate of MRSA from nares into the lower respiratory tract was 76% (16 out of 21 patients) in patients intubated nasally while none (0 out of 12) of the patients intubated orally showed MRSA growth on ETT tip culture. In study done by Corne P et al (2005) showed nasal carriage of MRSA to be the causative agent of Staphylococcal pneumonia in critically ill patients[15]

MRSA which are carried in anterior nares of normal humans can be carried to trachea during nasotracheal intubation. Chances of transfer of other micro-organisms to trachea are higher when intubation is done by nasal route. To conclude, we suggest screening for MRSA strains by nasal swabs prior to nasal intubation to prevent complication associated with carriage of these organisms to trachea.

Conflict of interest statement

We declare that we have no conflict of interest.

A RANDOMIZED, DOUBLE BLIND, PLACEBO-CONTROLLED STUDY OF PERI-OPERATIVE PREGABALIN FOR POST-OPERATIVE PAIN RELIEF IN PATIENTS UNDERGOING LOWER LIMB ORTHOPAEDIC SURGERY UNDER SPINAL ANAESTHESIA.

Pratik Tantia[1], S. Bano[2], Ruchi Saini[3]

SUMMARY

Introduction: Spinal anesthesia is the preferred technique for lower limb orthopaedic surgeries providing excellent operative conditions but with limited post-operative analgesia. Pregabalin is being used in the chronic pain arena for quite some time now but role in acute pain is not yet well defined.

Method: A randomized double-blind placebo controlled study including a total of 60 patients was designed to find the efficacy and safety of Oral Pregabalin as a protective analgesic.

Results: The time to rescue analgesic (VAS > 3) was 372.33±100.46 minutes in study group and 278.2±69.19 minutes in control group ($p < 0.0001$). The total dose of analgesics required (mg of Diclofenac) in study group (125 ± 49.57 mg) was less than the control group (162.5 ± 39.8 mg) but not statistically significant.

Conclusion: Oral Pregabalin was effective in increasing the duration of post-operative analgesia and reducing the dose of rescue analgesic required.

KEY-WORDS: Pregabalin, protective analgesia, post-operative analgesia

INTRODUCTION

"All is well that ends well". The reverse is also true as far as anesthesia and post-operative analgesia is concerned "Nothing is well if the end is not well". Acute post-operative pain (APOP), if untreated or inadequately treated can result in problems that can be a night-mare both to the patient and the attending doctor.

In an attempt to assert its significance, the Joint

CORRESPONDING AUTHOR: DR.PRATIK TANTIA, Senior Resident Address: Department of Anaesthesia, JNMCH, AMU, Aligarh, UP -202002. Phone nos.: 09368686647 E-mail: dr.tantia@gmail.com

Committee for Accreditation of Healthcare Organization has declared "pain as the fifth vital sign"; keeping in view the bensfits of aggressive management of APOP. Out of the desire to have a comfortable and pain-free patient in the post-operative period, efforts have been made and are going on throughout the world.

One such effort is the development of the concept of 'Preemptive analgesia', which aims at preventing the sensitization of the nervous system [1, 2]. This can be achieved by providing analgesia prior to the pain stimulus and continuing the same in the intra- and post-operative periods.

'Protective analgesia' is a technique that has grown as a part of preemptive analgesia wherein the drugs used are not primary analgesics but adjuvant drugs used in non-acute pain arena. Gabapentin and Pregabalin are being explored as protective analgesics [1,2].

Pregabalin is a synthetic analogue of GABA, acting as the $\alpha_2\delta$-subunit calcium channel ligand. Clinically it has analgesic, anti-convulsant, anxiolytic and sleep-modulating activities. By reducing the hyper-excitability of dorsal horn neurons that follows surgical trauma, Pregabalin does pose as an effective protective analgesic [3,4].

Majority of lower-limb orthopaedic surgeries are conducted under spinal anesthesia that provides profound analgesia. Untreated APOP may develop into chronic persistent neuropathic pain.

This study, therefore, was designed to evaluate the efficacy of peri-operative Pregabalin as protective analgesic in patients undergoing lower-limb orthopaedic surgeries under spinal anesthesia.

MATERIAL AND METHODS

After approval by the Institutional Ethics Committee, 60 ASA I/II adult (18-60 years) patients of either sex were enrolled in this prospective, randomized, double-blind, placebo-controlled study. They were to undergo elective lower-limb orthopaedic surgery under spinal anesthesia. Informed consent was obtained from all patients. All patients were examined in the PAC clinic/Bedside as per the Department's protocol.

Exclusion criteria for the study included patients having neurological or coagulation disorder, abnormal liver or renal function tests, valvular heart disease, hypotension, diabetes mellitus, Body mass index (BMI>30), emotional instability, unwillingness and any anticipated difficulty in regional anesthesia along with other contraindications of central neuraxial blockade.

Patients were then assigned to either of the two groups of 30 patients each with computer-generated randomization. They were to receive either study drug (Pregabalin 150 mg) or matching placebo at 1 hour before the spinal anesthesia and 7 hours after the first dose.

Anesthesia technique was standard for both the groups and started with pre-loading (500 ml of Ringer's lactate) over 15-20 minutes. Inj. Ondansetron 0.1 mg/kg was administered intravenously. Technique for spinal anesthesia included aseptic preparation and draping of the lower back. After identification of L_3-L_4 intervertebral space, lumbar puncture was done using 26 or 23 G Quincke spinal needle in sitting position. After confirmation of CSF flow, Inj. Bupivacaine 0.5% heavy, 2.5 ml was injected in subarachnoid space. Patient was then turned supine and monitors were attached (Pulse-oximeter, ECG and NIBP) and vitals recorded.

Parameters recorded

1. Pulse - Bradycardia was considered when pulse rate <

50/minute and was treated with Inj. Atropine 0.5 mg, if accompanied with hypotension.

2. BP - Hypotension was considered when systolic blood pressure showed a fall of more than 20% of the pre-operative level and was treated with Inj. Mephentermine 6 mg i.v. and crystalloid infusion.

3. SpO_2

4. Level of Sedation - This was noted as 4 point verbal rating scale

0 – No sedation
1 – Drowsiness
2 – Asleep but arousable
3 – Unarousable with loss of verbal contact

5. Total i.v. fluids and vasopressor required were noted.

6. VAS - In the post-operative period, pain was assessed using the Visual Analogue Scale at 30 minutes for the first 2 hours and then at 2 hourly intervals and next morning at 8 a.m.

7. Rescue analgesic - The time when the patient first complained of pain was noted and VAS score was assessed. VAS score more than 40 was considered significant and patient was given Rescue analgesic in the form of Inj. Diclofenac Sodium 1 mg/kg intravenous infusion.

8. Total analgesic required in the first 24 hours was noted.

9. Side Effects – Patients were asked for the following complaints: Nausea, Vomiting, Somnolence, Diplopia, Confusion and Urinary retention.

Statistical analysis was done using SPSS version 15. Since no previous data was available, sample size of 30 was taken as the minimum so as to ensure that the results were statistically significant (Central Limit Theorem). Student's t-test and Fisher's exact test were employed to find the significance of the results obtained. p-value < 0.05 was considered statistically significant. Power analysis was done post-hoc using the power and sample size calculator using the time to rescue analgesia and maximum pain scores. Cut-off limit for power of test was 80% ($\beta = 0.8$).

Aims of this study were to evaluate:

1. The duration of post-operative analgesia
2. Total dose of analgesics required in first 24 hours
3. Effect on hemodynamics
4. Side effects, if any, attributable to the drug

RESULT

Sixty patients were analyzed for the study in two groups of 30 each.

There was no statistically significant difference amongst the two groups with respect to age, sex or duration of surgery. (TABLE-1)

There was no difference amongst the two groups with respect to the site of surgery. (TABLE-2)

The hemodynamic parameters (intra and post-operatively) and the fluid and vasopressor requirement were comparable in the two groups. (FIGURES-1 & 2)

The time to rescue analgesic (VAS > 3) was 372.33±100.46 minutes in study group and 278.2±69.19 minutes in control group ($p < 0.0001$). The difference was extremely significant. (FIGURE – 3)

The total dose of analgesics required (mg of Diclofenac) in study group (125 ± 49.57 mg) was less than the control group (162.5 ± 39.8 mg) but not statistically significant. (FIGURE – 4)

Of the noted complications; nausea (3 patients in control group and 1 patient in study group), vomiting (1

in control), confusion (none), diplopia (0 in control, 1 in study), and urinary retention (1 in control, 2 in study), the two groups did not differ significantly. However, the incidence of Somnolence (2 patients in control group and 10 patients in study group) was significantly higher in study group.

CONCLUSION

We conclude that peri-operative Pregabalin has been effective in increasing the duration of post-operative analgesia and decreasing the total dose of analgesics required in early post-operative period without any significant changes in hemodynamic parameters or side-effects.

SUCCESSFUL SPINAL ANESTHESIA AFTER 'DRY TAP' IN A PATIENT HAVING CIRRHOSIS OF LIVER

Pratik Tantia[1], Sunny Malik[2], Mozammil Shafi[1], S. Bano[2]

SHORT TITLE: Spinal anesthesia after dry tap lumbar puncture in a patient with cirrhosis of liver and portal hypertension.

SUMMARY: We report a case of successful spinal anesthesia in a patient with cirrhosis of liver and portal hypertension. Attempts at lumbar puncture by an experienced anesthesiologist produced the typical 'give-in' feeling of dural puncture without obvious Cerebrospinal fluid (CSF) flow. At this point, it was decided to proceed and hyperbaric Bupivacaine was injected. Patient had successful neuraxial block within five minutes. The surgical and post-operative periods were uneventful.

KEY-WORDS: spinal anesthesia, dry tap, cirrhosis of liver

INTRODUCTION: Spinal (intrathecal) anaesthesia is generally regarded as one of the most reliable of regional block methods: the needle insertion technique is relatively straight-forward, with CSF providing both a clear indication of successful needle placement and a medium through which local anaesthetic solution usually spreads readily [1]. What if an experienced anesthesiologist, with all the precautions is unable to achieve the end point i.e. obvious CSF flow? 'Dry tap' on lumbar puncture has been reported previously; the usual cause being faulty technique. Causes include a blocked needle, needle in the wrong space, post-spinal surgery and low CSF pressure [2]. With some pathologic conditions, such as lumbar spinal-canal stenosis and adhesive arachnoiditis, a spinal puncture may result in a dry tap[3].

CASE HISTORY: 50-year-old female patient presented to the Emergency Room with complaint of pain in right hip-joint region following a trivial fall. X-ray examination confirmed the diagnosis of inter-trochanteric fracture of right femur. After initial conservative management, patient was to be operated for Dynamic-Hip-Screw fixation. On pre-anesthetic evaluation, significant history included low-grade fever, pedal edema and abdominal distension for the past 7 days and post-menopausal status for the past 4 years. On examination, patient was cachexic with moderate pallor, pedal edema and abdominal distension. Blood pressure (BP) was 200/110 $mmHg^{-1}$. Other examinations including airway and lumbar spine were normal. Investigations were ordered to find out the cause of hypertension and ascites. Hematological investigations: Hemoglobin-9 gdl^{-1}, Platelet count160,000 mm^{3}, Total Leucocyte count8000 mm^{3} and normal Differential Leucocyte count. Renal function tests: serum Creatinine1.3 $mgdl^{-1}$ and blood Urea-50 $mgdl^{-1}$. Chest X-ray showed evidence of cardiomegaly. Electrocardiogram findings were suggestive of Left Axis Deviation. Echocardiography

findings were suggestive of Left ventricular hypertrophy with normal valves and no regional wall motion abnormality. Ultrasonography showed free fluid in abdominal cavity with cirrhotic changes in the liver. Liver function tests: total serum Bilirubin-1.8 $mgdl^{-1}$, Enzymes in high normal range, serum Proteins-5 gdl^{-1}, Albumin: Globulin2.1:1. Tests for coagulation: Prothrombin time20 seconds with International Normalized Ratio1.6. The physician prescribed Amlodipine 10 mg, Torsemide 5 mg and Spironolactone 25 mg to be taken once daily. These medications along with abdominal paracentesis helped resolve the ascites and optimize the BP within 7 days. Patient was then taken up for surgery. Informed consent was taken. Accordingly a plan for spinal anesthesia was made and patient was directed about the fasting status. Pre-operatively, patient had a pulse rate of 90 min^{-1}, regular and BP of 120/70 $mmHg^{-1}$.

Patient was taken first in the morning and after premedication with Ondansetron 4 mg and preloading with 500 ml 0.9% Sodium Chloride solution; she was shifted to the Operating Room. Monitors attached included Pulse-oximeter, Non-invasive Blood Pressure (NIBP) and Cardioscope. She was put in sitting position for spinal anesthesia and under strict aseptic precautions the back was prepared. An experienced anesthesiologist attempted Lumbar puncture in L_3-L_4 intervertebral space (IVS) with 23 guage Quincke spinal needle. Even after three attempts that produced the typical 'give-in' feeling of dural puncture and changing the IVS to L_2-L_3 no CSF was seen. Negative aspiration failed to show CSF flow. It was then decided to inject 2.5 ml of hyperbaric Bupivacaine 0.5% at this point of 'give-in' feel, with the realization that even if the needle was not in the subarachnoid space, the low amount of drug would not cause a major problem. Patient was then immediately put in supine position and all the pressure points were adequately padded. Assessment of motor and sensory blocks was confirmatory. A sensory block (assessed using pin-prick method) upto T_6 was attained within 5 minutes and the surgeons were asked to proceed. Surgery lasted for 60 minutes and completed uneventfully. Sensory block regression was adequate, reaching L_1 level after another 90 minutes. The post-operative period was uneventful over the next 48 hours.

DISCUSSION: Regional anesthesia in the form of central neuraxial blockade has definite advantage over general anesthesia for patients undergoing lower-limb orthopedic surgery. This includes reduction in the incidence of major peri-operative complications with certain surgical procedures including deep vein thrombosis, pulmonary embolism, blood loss, respiratory complications and death [4]. Post-operative pain management, a significant problem after orthopedic procedures, with regional anesthetic techniques, leads to superior pain relief [5]. Also, no airway manipulation, minimal drug use and a conscious patient was of utmost importance in our case.

Spinal anesthesia is a reliable and relatively simple technique of central neuraxial blockade for lower limb orthopedic surgeries. A major advantage of spinal anesthesia is its definitive endpoint i.e., the free flow of CSF [6]. Two conditions are, therefore, absolutely necessary to produce spinal anesthesia: puncture of the duramater and subarachnoid injection of an anesthetic agent[7]. This is possible only when CSF flow is seen.

However, sometimes one may not get an obvious CSF flow on lumbar puncture, i.e. 'dry tap'. Usual causes include faults in the technique employed and can be corrected by adhering to the basic rules. Occasionally, the dry tap may be genuine, wherein after the typical 'give-in' feeling of dural puncture, no CSF flow is seen. Causes include previous spinal surgery, low CSF pressure or pathologic conditions like adhesive arachnoiditis and lumbar spinal-canal stenosis.

Our patient, middle aged postmenopausal female, presented with fracture of femur after a trivial injury. Incidentally, she was found to have anemia, systemic hypertension and cirrhosis of liver with portal hypertension and ascites. After optimizing the patient's condition with anti-hypertensives and diuretics, she was to be operated under spinal anesthesia. An experienced anesthesiologist was faced with 'dry tap'. Keeping in view the patient's request to be operated under regional anesthesia and the negligible risk involved with injection of small quantity of local anesthetic in wrong space, it was decided to inject Bupivacaine at the point where the typical 'give-in' feeling of dural puncture was appreciated. The subarachnoid block was successful with adequate sensory and motor block leading to an uneventful surgery. The patient had excellent pain relief in the early post-operative period which was later supplemented with systemic analgesics.

The possible causes of 'dry tap' in our patient could have been low CSF pressure [8] resulting from diuretic

therapy as other pathological causes could be ruled out on the basis of absence of symptoms, negative history and absence of infectious etiology. Epidural could have been an option, but accidental dural puncture would go unrecognized. Other techniques for verification of needle location include radiological imaging with contrast studies or real-time stimulation testing with insulated needle [9], both of which were not feasible in our case.

CONCLUSION: To conclude, it is not intended that local anesthetic be given in every case of dry tap, as most often the cause is a faulty technique. We report this case, as 'dry tap' had been encountered and spinal anesthesia was successful suggesting that the 'dry tap' was genuine.

Abstract

Objective: The present study was performed to evaluate the effectiveness of intravenous Clonidine as a part of premedication in controlled hypotensive anaesthesia during functional endoscopic sinus surgery (FESS). **Material & Methods:** It was a prospective study carried out in the department of Anaesthesia of a tertiary care centre of Rajasthan, India. 50 patients undergoing FESS surgery for chronic sinusitis were included in the study and were divided into two groups viz. group I, who were given normal saline and group II, who were given intravenous Clonidine 3µ/kg as a part of premedication prior to induction. The outcomes were measured by estimation of mean arterial pressure (MAP), extra requirement of isoflurane and nitroglycerine (NTG) to achieve target MAP, blood loss during the surgery, duration of surgery and post-operative complications. **Results:** Both the groups were matched in terms of age, sex and weight parameters. There was statistically significant difference between MAP in group I and group II before induction, average intra-operative and during immediate post-operative period. The requirement of extra isoflurane or NTG to achieve target MAP was high (in 56% patients) and moderate (in 44% patients) in group I while low requirement was needed in 60% of group II cases and rest 40% cases didn't required any extra isoflurane or NTG. The average amount of blood loss in group II was significantly less (230±66 ml) than group I (356±75 ml). Similarly, the duration was 76±16 minutes in group I surgery and 59±12 minutes in Clonidine group. Quality of surgical field as per Boezart score was significantly better in Clonidine group. The incidence of postoperative complications like bradycardia, hypotension and prolonged sedation were not significant in both the groups. **Conclusion:** Clonidine is cheap and safe drug to use for controlled hypotensive anaesthesia without any significant side effect in FESS.

Key Words: Clonidine, Controlled anaesthesia, Hypotension, Sinus surgery, Bradycardia

INTRODUCTION

Functional endoscopic sinus surgery (FESS) has been emerged as treatment of choice for chronic rhinosinusitis with or without nasal polyp refractory to medical treatment. During the surgery, even a small amount of bleeding can decrease visibility of the surgical field and is directly related to increased risk of complications and surgery failure.[1] Hence it is important to minimize bleeding during the surgery. Preoperative preparation using antibiotic and steroid medications, intra-operative use of local decongestant and hypotensive anaesthesia by an expert anaesthetist are the methods which are being

used to control bleeding during FESS and better visualization of surgical field. Many drug combinations and protocols for controlled hypotensive anaesthesia have been used and compared in past years. Two main strategies being used for hypotensive anaesthesia are (a) deep anaesthesia with strong analgesia and (b) standard anaesthesia with hypotensive drugs. The first strategy may result in prolonged recovery while second strategy may result in postoperative hypotension. Hence, achieving controlled hypotensive anaesthesia in FESS is challenging and important for surgeon as well as anesthetist.Alpha2 agonists have been used in controlled hypotensive anaesthesia for decades. In addition to their antihypertensive and sympathicolytic effect, they are known to have effective sedative and analgesic effect with hemodynamic stability.[2] In present study, we are assessing the effect of single iv dose of Clonidine for controlled hypotensive anaesthesia in FESS surgery. The results were compared with placebo group.

MATERIAL AND METHODS

The present study was a prospective study carried out in the department of anaesthesia, Ananta Institute of Medical sciences, Rajsamand during the period of 1 year from December 2017 to December 2018.50 patients of chronic rhinosinusitis with or without nasal polyposis who were to undergo functional endoscopic sinus surgery (FESS) were included in the study. Patients were randomly allocated to two groups with 25 members in each group. Pre- anaesthesia examination of all the patients was done a day before surgery.

Group I- received 20 ml of normal saline in premedication.

Group II- received 3µg/kg body weight in 20 ml normal saline in premedication.

Exclusion criteria:

1. Patient with history of hypertension, cardiovascular accidents, ischaemic heart disease, hepatic and/ or renal dysfunction or poor respiratory reserve.
2. Pregnant or lactating female.
3. History of allergy to any of the drugs to be used during the study.
4. Patients already using the drugs that may affect the results of present study (anticoagulants, calcium channel blockers, beta-blockers, clonidine).
5. Obese patients weighing > 90 kg.
6. Patients having history of FESS done in the past.
7. Patients refused to give consent.

Ethical clearance: approval from institutional ethical committee was taken before starting the study and well informed consent was also taken from all the patients involved in the study.

RESULTS

The study was conducted during the period of 1 year from December 2017 to December 2018.50 patients of chronic rhinosinusitis with or without nasal polyp who were to undergo FESS surgery and who met the inclusion criteria were included in the study. Patients were randomly divided into two groups. Group I was the placebo group in which the patients were given 20 ml of normal saline as part of premedication while in group II, patients were given Clonidine 3µg/kg in 20 ml of normal saline as part of premedication. Both the groups were matched in terms of age and sex and weight parameters. (Table 1)

Table 1: Age, sex and weight of the patients included in present study

Parameters	Group I	Group II
Age (mean age in years)	42.62	44.91
Sex (M:F ratio)	16:9	17:8
Weight (mean weight in kg)	67.97	63.88

There was statistically significant difference between MAP in group I and group II before induction, average intra-operative and during immediate post-operative period. The MAP after induction in group I and II were 83±12 mmHg and 79±11 mmHg respectively but the difference was not statistically significant. (Table 2)

Table 2: Mean Arterial Pressure of the patients of two groups in the study

Mean Arterial Pressure (MAP)	Group I	Group II	p-value
Before induction	102±14	89±12	0.0009
After induction	83±12	79±11	0.2252
Average intra-operative	73±6	68±4	0.0011
Immediate post-operative	101±8	84±7	0.0001

The requirement of extra isoflurane or NTG to achieve target MAP was high (in 56% patients) and moderate (in 44% patients) in group I while low requirement was needed in 60% of group II cases and rest 40% cases didn't required any extra isoflurane or NTG. (Table 3)

Table 3: Extra requirement of isoflurane or NTG in two groups of the study

Requirement	Group I	Group II
High	14	0
Moderate	11	10
Low	0	15

The average amount of blood loss in group I surgery was 356±75 ml while in group II surgery, it was 230±66 ml and the difference was statistically significant. Similarly, the duration was 76±16 minutes in group I surgery and 59±12 minutes in group II surgery and the difference was statistically significant. (Table 4)

Table 4: Amount of blood loss and duration of surgery in two groups of the study

	Group I	Group II	p-value
Blood loss (ml) (Mean±SD)	356±75	230±66	0.0001
Duration of surgery (Mean minutes±SD)	76±16	59±12	0.0001

Quality of surgical field as measured by Boezart score was good in 8% of group I cases and 32% of group II cases, fair in 80% of group cases and 64% of group II cases, poor in 20% of group I cases and only 4% of group II cases. (Table 5)

Table 5: Quality of surgical field in two groups of the study

Grade	Group I	Group II
Good (0-1)	2	8
Fair (2-3)	20	16
Poor (4-5)	5	1

20% of group I patients had complications (hypotension 8%, Bradycardia 8% and prolonged sedation 4%) and 28% of group II patients developed complications (hypotension 12%, bradycardia 8% and prolonged sedation 8%). (Table 6)

Table 6: Incidence of post-operative complications in present study

Complications	Group I	Group II
Hypotension (< 50mmhg)	2	3
Transient Bradycardia	2	2
Prolonged sedation	1	2
Total	5	7

DISCUSSION

FESS is the preferred surgical method to treat chronic sinusitis which are refractory to medical treatment. Bloodless field is often required in FESS for better visibility of surgical field and to avoid complications and failure. Many pre-operative and intra-operative strategies have been explored till now to minimize the risk of bleeding in patients undergoing FESS. The success of these strategies is determined based on their impact on amount of blood loss during surgery, duration of surgery, quality of surgical field explained by surgeon and post-operative complications. Various methods are pre-operative antibiotics and steroids, position of the patient (reverse Trendelenburg position), intra-operative use of local decongestant, local vasoconstrictor injections, warm saline irrigation, controlled hypotensive anaesthesia and use of tranexemic acid.[4] The present study is a placebo-controlled study performed to assess the hypotensive effect of intravenous Clonidine in FESS surgery. In present study, we successfully achieved the target MAP between 50-70 mmHg in all the patients. The average MAP during intra-operative period in group I and group B were 73±6 mmHg and 68±4 mmHg respectively. Thus, it was observed that average MAP was significantly lower in Clonidine group than placebo group. Further, to achieve the target MAP, there was high to moderate requirement of extra isoflurane or NTG in placebo group while very less requirement was there in Clonidine group. (Table 3)Similar results were observed in a study done by V. A. Praveen and R. Krishna Prabu in 2016. They studied the effect of Clonidine as a part of hypotensive anaesthesia for FESS and found that 60% patients of placebo group required high amount of extra isoflurane and NTG while in clonidine group, there was very less requirement of extra isoflurane and NTG to achieve target MAP. [5] Similar results were obtained in other studies by Jabalameli *et al*, Hackmann *et al*, Howie *et al*. and Engelman E *et al*. [6, 7, 8, 9] The average amount of blood loss in Clonidine group (230±66 ml) was significantly less than placebo group (356±75 ml) in present study. The results were similar to another study done by Okuyama *et al* in 2005. They studied the effects of clonidine and prostaglandin E1 on blood loss during FESS and concluded that Clonidine constricts peripheral blood vessels and reduces nasal mucous blood flow which accounts for the reduction of blood flow. [10] Jabalameli *et al* also had the similar results with their studies on effect of Clonidine on reducing bleeding in FESS. The average duration of surgery was also very less in Clonidine group (59±12 min) as compared to placebo group (76±16 min). The results were similar to studies done by Nair S *et al* and Wawrzyniak *et al*. [11, 12] In present study, the surgical field grading showed that Clonidine group had better grading than the placebo group. The results were highly correlated with results of past studies done by Jabalameli M *et al* and Anvari *et al*.[6,13] 28% cases from clonidine group developed complications like hypotension (in 12% cases), bradycardia (in 8% cases) and prolonged sedation (in 8% cases) but the complications were not severe and relieved without any treatment. 20% cases from placebo group developed similar complications. The incidence of complications was similar in both the groups. Similar results were obtained by Meghna Jivanmall *et al* in their study to assess the effect of intravenous Clonidine in FESS. They also used 3µg/kg Clonidine in premedication and compared the results with placebo group. The incidence of complication between two groups was statistically insignificant. Out of 30 patients in Clonidine group, 3 patients had prolonged sedation, 10 patients had hypotension and 1 patient had bradycardia. The results were highly correlated with the results of present study. [14]Similar results were obtained by Sahajananda and Rao *et al* and Samantaray *et al*. They also used 3µg/kg Clonidine as a part of premedication and observed no significant incidence of complications like hypotension,

bradycardia which required treatment and thus correlates better with the results of present study.[15,16]

CONCLUSION

A single intravenous dose of Clonidine (3μ/kg) as a part of premedication is effective to achieve controlled hypotensive anaesthesia in FESS. It maintains the mean arterial pressure within limits without additional requirement of isoflurane or NTG. It significantly reduces the amount of blood loss and provides a better field of visibility for surgery and thus shortens the duration of surgery. Clonidine is cheap and safe drug to use for controlled hypotensive anaesthesia without any significant side effect.

Abstract

Objectives: The present study was carried out to assess the role of caudal epidural injections of steroid with local anesthtic in the management of chronic low-back pain. *Materials and Methods:* Fifty patients of chronic low-back pain were included in the study. Epidural injections of steroid with local anesthetic were administered to them via caudal approach. Follow up was scheduled after 1 month, 3 months, and 6 months. Assessment was done by using VAS score and ODI. *Results:* Fifty patients of chronic low-back pain were included in the study. 31 (62%) patients were male and 19 (38%) were female. Age of the patients ranges from 30 to 70 years with the mean age of 55.21 years. Mean VAS score of the patients before the intervention was 7.91 ± 1.60 which was reduced to 3.87 ± 1.21 at 1 month follow-up, 3.46 ± 1.32 at 3 months follow-up and 4.66 ± 1.56 at 6 months follow-up. Similarly, mean ODI of the patients before the treatment was 53.81 ± 6.12 which was reduced to 33.67 ± 4.89 at the end of 1 month, 32.65 ± 5.11 at the end of 3 month and 28.80 ± 4.71 at the end of 6 month. *Conclusion:* Caudal epidural injection of steroid with local anesthetic is an effective method for the management of chronic low-back pain in terms of pain relief and functional improvement in both short- and long-term results.

Keywords: Chronic low back pain; Steroid; Local anesthetic; Epidural; Radiculopathy; Spinal stenosis.

Introduction

Chronic low-back pain is a common community health problem worldwide. Over 70% people in developed countries experience low-back pain at sometime in their lives.[1] In India, this figure is even more around 80%. Every year, around 3–4% of population in India is temporarily disabled, and 1% of working age population is disabled totally and permanently because of low-back pain.[2]

Low-back pain is defined as pain, muscle tension or stiffness localized below the costal margin and above the inferior gluteal folds with or without leg pain and it is defined as chronic when the duration of pain is 12 weeks or more.[3]

The origin of low-back pain can be various anatomic structures like muscles, fascial structures, nerve roots, bones, joints, intervertebral discs, and abdominal organs. Many times, the pain can arise from aberrant neurological pain processing which causes neuropathic low-back pain.[4,5]

Furthermore, low-back pain can also be influenced by psychological factors (like anxiety, depression and stress, etc.) and psychosocial factors.[6–8]

Hence, the diagnosis of low-back pain is very challenging and must include thorough history taking about the symptoms as well as about psychological and psychosocial factors. A proper clinical examination and identification of origin of pain is the mainstay of diagnosis. Radiological investigations including MRI/CT scan should be advised wherever necessary.

Till now, various conservative, surgical and non surgical methods have been used for low-back pain with variable results.[9-13] Every patient with low-back pain is not a candidate for surgery and, in fact, surgery had been proven failure in approximately 25% of well selected cases.[14]

A cornerstone of non-surgical treatment for low-back pain is epidural steroid injection and still is the most commonly performed procedure for low-back pain.[10-13]

There are three different ways to perform epidural injection, viz. caudal block, translumbar approach and transforamial approach. In present study, we are using caudal epidural injection (CEI) approach to administer steroid and local anesthetic (LA) agent for the management of low-back pain.

Materials and Methods

The present study is a prospective study carried out in the department of anesthesia, Ananta institute of medical sciences, Rajsamand during the period of 1 year from January 2018 to January 2019. Fifty patients attended orthopedic OPD with the complaints of low-back pain were included in the study.

Sample size and sampling: Fifty patients of chronic low back pain.

Study type: Quantitative, Prospective

Duration of study: 1 year

Inclusion criteria

1. Pain on the low-back region, buttock and/or lower extremities while standing, walking and/or spinal extension.
2. Mild-severe lumbar central canal spinal stenosis identified by CT/MRI.
3. Lower extremity symptoms consistent with neurogenic claudication.
4. Must provide consent for study and should be able to complete the assessment instruments.
5. Age ≥ 30 years.

Exclusion criteria

1. Other comorbidities that could interfere with the results of the study concerning pain and function like painful peripheral neuropathy, fibromyalgia, Parkinson disease, dementia, stroke, amputees, other neurological disorders
2. Spinal instability requiring surgical fusion.
3. Severe osteoporosis
4. Known hip joint pathology
5. Bone metastasis
6. Allergy to local anesthetic and/or steroid.
7. Tuberculosis or other bone infection
8. Any other systemic disorder that limits ambulation of patient

Technique

The procedure was carried out in the operation theater. The patients were laid in prone position with a pillow in their inguinal region. Sacral hiatus was palpated and a 22G spinal needle was preceded into the hiatus at an angle of 45. Reaching the bone structures, the angle reduced to 10 and after preceding about 5 cm, hiatus was entered and epidural region was attained. Injection containing 2 ml (80 mg) methyl prednisolone with 4 ml of 2% xylocaine was injected into the epidural space without fluoroscopic guidance.

Data collection tool (score) used: Pain was assessed by using visual analogue scale (VAS) score (1-10). Functional status was assessed by using Oswestry disability index 2.0 (ODI).[15]

Follow-up: Follow up was scheduled at 1, 3 and 6 months.

Ethical clearance was taken from institutional ethical committee. Informed written consent was obtained from all the patients involved in the study.

Results

Fifty patients of chronic low back pain who met the inclusion criteria were included in the study. 31 (62%) patients were male and 19 (38%) were female. Age of the patients ranges from 30 to 70 years with the mean age of 55.21 years.

Mean VAS score of the patients before the

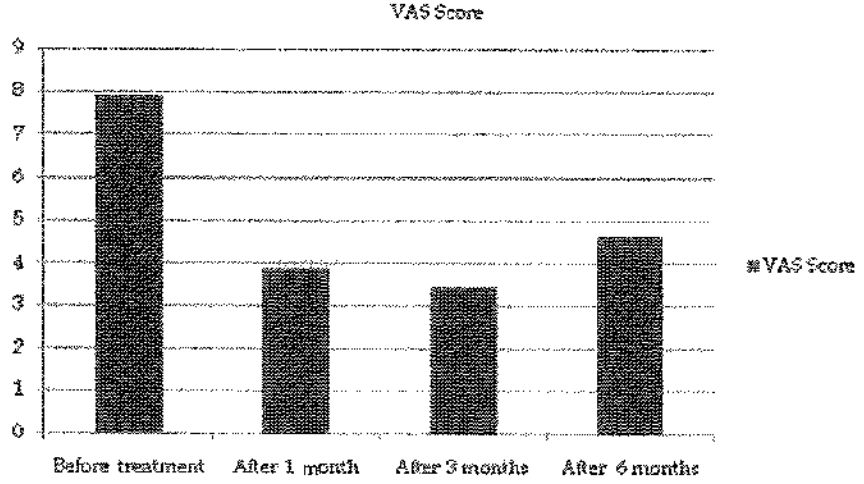

Fig. 1: MeanVAS score of the patients before treatment and at 1, 3, 6 month follow up.

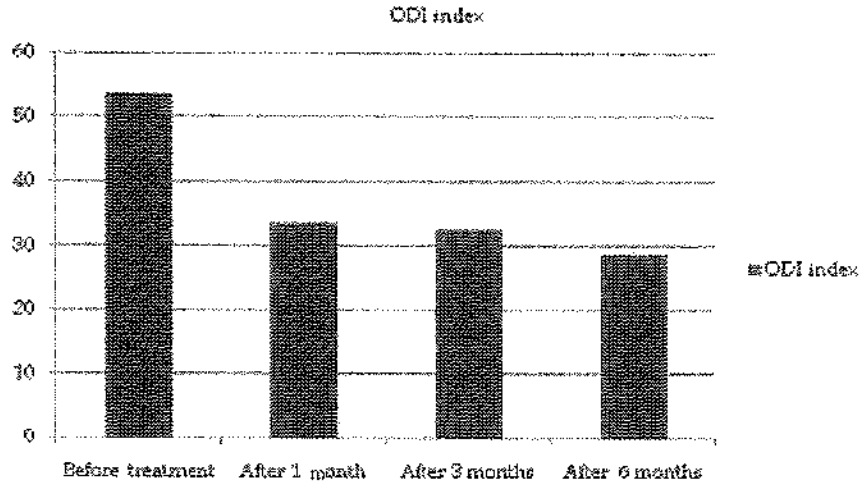

Fig. 2: Mean ODI before treatment and at 1, 3, 6 month follow up.

intervention was 7.91 ± 1.60 which was reduced to 3.87 ± 1.21 at 1 month follow-up, 3.46 ± 1.32 at 3 months follow-up and 4.66 ± 1.56 at 6 months follow-up. When compared to the VAS score before the treatment, the results were statistically significant (p-value < 0.05). Mean VAS score at six months follow up was higher than previous follow up values but the difference was not found to be statistically significant (p-value > 0.05) (Fig. 1).

In present study, mean ODI of the patients before the treatment was 53.81 ± 6.12 which was reduced to 33.67 ± 4.89 at the end of 1 month, 32.65 ± 5.11 at the end of 3 month and 28.80 ± 4.71 at the end of 6 month. When ODI values at each follow up was compared with ODI before treatment, the difference was statistically significant (p-value < 0.05) but when the ODI values at each follow up were compared with each other, the difference were not significant (p-value > 0.05) (Fig. 2).

Discussion

The present study was carried out to assess the role of caudal epidural injections of steroid with local anesthtic in the management of chronic low-back pain. The study showed positive outcome in both short- and long-term results in terms of reduction

in pain as well as good functional outcome.

The improvement in pain after epidural injections was assessed using VAS score. The mean VAS score of the patients before the intervention was 7.91 ± 1.60 which was reduced to 3.87 ± 1.21 at 1 month follow-up, 3.46 ± 1.32 at 3 months follow-up and 4.66 ± 1.56 at 6 months follow up. When compared with initial VAS score, the difference at follow up was statistically significant (p-value < 0.05), suggestive of positive outcome in both short- and long-term period. The VAS score at 6 months follow up was little higher than the previous follow up but the difference was not statistically significant (p-value > 0.05).

The improvement in mobility and function was assessed using ODI (Oswestry Disability Index).

ODI is calculated based on each score of the ODQ (Oswestry Disability Questionnaire), which consists of ten items. Each of the ten items is scored from 0 to 5, and the total is added and multiplies by 2. Therefore, the ODI ranges from 0 to 100.[15]

In present study, mean ODI of the patients before the treatment was 53.81 ± 6.12 which was reduced to 33.67 ± 4.89 at the end of 1 month, 32.65 ± 5.11 at the end of 3 month and 28.80 ± 4.71 at the end of 6 month. The difference was found to be statistically significant when ODI at each follow up was compared with ODI before treatment (p-value <0.05). The results are suggestive of good positive outcome in both short- and long-term follow up.

Manchikanti *et al.* performed a similar study in 2010 which included 70 patients of discogenic low-back pain. They compare the effect of caudal epidural injections (CEIs) of steroid and LA with CEIs of LA alone. Results were assessed using VAS, ODI, employment status and opioid intake. They got positive outcome for both short- and long-term results in both the groups. (86% in steroid + LA group and 74% in LA alone group). The results suggested that CEIs of steroid with LA are more effective than CEIs of LA alone in treatment of discogenic low-back pain.[16]

Ghahreman *et al.* also performed a comparative study in 2010 with 150 patients of low-back pain radiating to lower limb and concluded that CEIs of steroid with LA were effective than intramuscular injections in pain reduction secondary to radiculopathy.[17]

Wilson-Macdonald *et al.* performed a study in 92 patients of disc prolapse or spinal stenosis. They compared the effect of CEIs of steroid and LA with that of intramuscular injection of the same in the management of chronic low-back pain due to disc prolapsed or spinal stenosis. The assessment methods used were Oxford pain chart and ODI. They concluded that CEIs of steroid with LA was more effective in short-term results but was not found beneficial over intramuscular injections in long-term results.[18]

Iversen *et al.* also performed a study in 2011 to compare the effect of CEIs of steroid with that of placebo. 133 patients with unilateral lumbar radiculopathy were included in their study. The results were in contrary to our findings. They concluded that CEIs of steroid had no benefit over placebo in treating lumbar radiculopathy.[19]

Arden *et al.*, in 2005, studied the effect of CEIs of steroid with LA in 228 patients of sciatica and concluded that CEIs of steroid with LA had only short-term benefit over placebo in treating sciatica. Thus the results were partially in favor of present study.[20]

Bush K and Hillier S performed a placebo controlled study to assess the effect of CEIs of steroid with LA in the management of intractable sciatica and found that after 1 year follow up; subjective and objective measures were improved in both the groups. The improvement was greater in actively treated group but only the objective assessment, i.e. straight leg raise, was statistically significant.[21]

Another study done was by Breivik H *et al.* in the year 1976. Thirty-five patients of chronic lumbar radiculopathy were included in the study and a comparative assessment was done between the effect of CEIs of bupivacaine and methylprednisolone with bupivacaine followed by saline. They found improvement in both the groups but the improvement was greater in treatment group.[22]

In present study, caudal epidural injections of steroid with local anesthetic were found to be highly effective in both short- and long-term follow up. Both the VAS and ODI were improved till the 6 months follow up. ODI was slightly reduced at 6 months follow up than the previous value but the difference was not statistically significant.

An important limitation of present study was that we did not extend our treatment to control items for the comparison due to limitations of the time course. Replication of treatment results with the use of other control items would have provided a strong demonstration of experimental control,

strengthening the results of the study.

Conclusion

The results of the present study showed that caudal epidural injections of steroid with local anesthetic is an effective method for the management of chronic low-back pain in terms of pain relief and functional improvement. The results of present study are in favor of many studies done in the past but in contrary to some other studies. An important limitation of present study was that control items were not included in the treatment strategy. In future, controlled studies with large sample group and systematic reviews of various such studies are expected for further useful outcomes in the management of chronic low-back pain.

What this study adds to existing knowledge

The present study advocates the use of epidural steroid with local anesthetic injections for the management of chronic low-back pain. In comparison to previous study of using steroid alone or LA alone, the combination of steroid and LA have better results in both short- and long term follow up. Further, many patients in developing countries live with disability to avoid surgery but CEIs can be an effective alternative for them.

Comparative Study of Using Intrathecal Clonidine and Fentanyl as an Adjuvant to Hyperbaric Bupivacaine (0.5%) in Lower Abdomen Surgeries

Suman Kaushik

Associate Professor, Department of Anaesthesia, Ananta Institute of Medical Sciences, Rajsamand, Rajasthan.

ABSTRACT

Objective: The present study was carried out to compare the effect of intrathecal Clonidine and intrathecal Fentanyl as an adjuvant to hyperbaric Bupivacaine in terms if efficacy, safety and post-operative analgesia in patients undergoing lower abdominal surgeries.

Material and methods: 100 patients planned for elective lower abdominal surgery under spinal anaesthesia were included in present study. The patients were divided into two groups viz. group I (n=50) in which patients were given 2.5 ml of hyperbaric Bupivacaine (0.5%) with 50µg of Clonidine intrathecally and group II (n=50) in which patients were given 2.5 ml of hyperbaric Bupivacaine (0.5%) with 25µg of Fentanyl intrathecally. Assessment was done in terms of time taken for onset of sensory and motor blockade, duration of sensory and motor blockade and requirement of rescue analgesia.

Results: Patients' age, height, weight, sex ratio, mean arterial pressure during surgery (MAP), heart rate (HR) and duration of surgery were not significantly different between two groups. Onset of sensory blockade was significantly lower in Fentanyl group (group II) (2.02±0.15 min) while onset of motor blockade was significantly lower in Clonidine group (group I) (4.62±1.21 min). Duration of sensory and motor blockade was significantly less in Fentanyl group. Time for requirement of first dose of analgesia was also significantly longer in clonidine group (490.55±28.98 min) when compared to fentanyl group (421.19±26.64 min).

Conclusion: addition of 50µg Clonidine to hyperbaric Bupivacaine as an adjuvant in spinal anaesthesia for lower abdominal surgeries offers longer post-operative analgesia than Fentanyl with no side effects.

Keywords: Clonidine, Bupivacaine, Spinal, Fentanyl, abdominal surgery

INTRODUCTION

Bupivacaine is most commonly used local anaesthetic for spinal anaesthesia but the duration of anaesthesia is short and limited. Short duration of action can be overcome by using large doses of Bupivacaine but it can produce serious cardiac toxicity. Perioperative hemodynamic stability is also a concern. Hence, to address the problem of short duration of action and to improve perioperative hemodynamic status and quality of analgesia, various adjuvants are being used intrathecally along with Bupivacaine. [1,2] Various adjuvants used are Midazolam, opioids, neostigmine, Dexmedetomidine, and Clonidine. [3]

Fentanyl (µ1- and µ2- receptor agonist) is most common opioid used as an adjuvant to local anaesthetic in spinal anaesthesia. It has rapid onset and short duration of action along with minimal cephalic spread. However, it also has some side effects like nausea, vomiting, pruritis, respiratory depression and urinary retention. [4,5]

Clonidine is a selective alpha-2 receptor agonist agent, routinely used as

premedication agent for general anaesthesia. It prolongs sensory and motor block in spinal anaesthesia and provides prolonged postoperative analgesia. It acts by indirectly inhibiting the activity of wide dynamic range (WDR) neurons.

In present study, we have compared the effect of intrathecal Clonidine and intrathecal Fentanyl as an adjuvant to hyperbaric Bupivacaine in terms if efficacy, safety and post-operative analgesia in patients undergoing lower abdominal surgeries.

MATERIALS AND METHODS

The present study is a prospective study carried out during the period of one year from October 2016 to October 2017, after obtaining approval from institutional ethical committee and properly informed written consent from all the participants.

100 patients planned for elective lower abdominal surgery under spinal anaesthesia were included in present study. The patients were pre-medicated with glycopyrrolate 0.2 mg intravenous (IV) and ondansetron 4mg (IV). Sedatives were not used during whole procedure. In the operation theatre, the baseline parameters (pulse, blood pressure, SpO2, electrocardiogram) were recorded and preloading was done with Ringer lactate solution 10-15/kg. The patients were divided into two groups:

Group I (n=50): patients were given 2.5 ml of hyperbaric Bupivacaine (0.5%) with 50µg of Clonidine intrathecally.

Group II (n=50): Patients were given 2.5 ml of hyperbaric Bupivacaine (0.5%) with 25µg of Fentanyl intrathecally.

Exclusion criteria:

1. Patients with systemic disorders like diabetes, hypertension, and heart disease with ASA grade more than II.
2. Allergy to drugs used in the study.
3. Patients with contraindication to spinal anaesthesia like spine deformity raised intracranial pressure, neurological disorders, bleeding disorders or infection at puncture site.
4. Patient's refusal to give consent for the procedure.

Procedure: Under all aseptic precautions, subarachnoid block was administered with 23 G spinal needle through mid-line approach in sitting position. Intrathecal (IT) drug was injected in L3-L4 intervertebral space over 30 seconds. After the block was performed, the patients were made supine and were given supplemental oxygen. Bradycardia and hypotension were treated with IV atropine and ephedrine, respectively.

The following parameters were noted after subarachnoid block:

- Time of onset of sensory block (tested by pinprick method)
- Time taken for onset of motor blockade (assessed by modified Bromage scale: Bromage 0: Patients able to move hip, knee, and ankle, Bromage 1: Patients unable to move hip but able to move the knee and ankle, Bromage 2: Patient unable to move hip and knee but able to move the ankle, Bromage 3: Patient unable to move hip, knee, and ankle). [6]
- Intra operative haemodynamic monitoring (heart rate (HR), systolic blood pressure (SBP) measured immediately after subarachnoid block, 2nd min, 5th min, 10th min and every 5 min till the end of surgery)
- Total duration of analgesia (time from the onset of analgesia to the point where the patient complained of pain at the surgical site requiring rescue analgesia)
- Duration of motor block (complete recovery of motor power).

RESULTS

100 patients undergoing lower abdominal surgery under spinal anaesthesia were included in the study and divided into two groups viz. group I, in which Clonidine was used along with hyperbaric Bupivacaine and group II, in which Fentanyl was used along with hyperbaric Bupivacaine.

Patients' age, height, weight, sex ratio, mean arterial pressure during surgery

(MAP), heart rate (HR) and duration of surgery were not significantly different between two groups. (Table 1)

Table.1 Baseline characteristics of the study participants in two groups

S. No.	Parameters (Mean±SD)	Group-I	Group-II	P-value
1	Age (years)	38.61±9.22	40.01±10.48	0.4799
2	Height (cm)	148.77±9.47	146.89±9.09	0.3114
3	Weight (Kg)	61.09±6.21	62.98±6.66	0.1454
4	Sex (M:F)	36:14	38:12	1.0000
5	MAP (mmHg)	84.68±5.87	85.43±5.32	0.5048
6	HR (bpm)	82.11±4.97	83.01±4.34	0.3372
7	Duration of Surgery (min)	92.56±12	95.44±65	0.7587

Table 2 shows the comparison of blockade between two groups in terms of onset and duration of sensory and motor blockade and requirement of first dose of rescue analgesia. Onset of sensory blockade was significantly lower in Fentanyl group (group II) while onset of motor blockade was significantly lower in Clonidine group (group I). Duration of sensory and motor blockade was significantly less in Fentanyl group. Time for requirement of first dose of analgesia was also significantly less in Fentanyl group when compared to Clonidine group. (Table 2)

Table.2 Comparison of blockade and analgesia effect of two groups

S.No.	Parameters	Group-I	Group-II	P-value
1	Onset of sensory blockade (min)	2.11±0.12	2.02±0.15	0.0013
2	Onset of motor blockade (min)	4.62±1.21	5.36±1.45	0.0067
3	Duration of sensory blockade (min)	170.87±14.43	129.32±11.31	0.0001
4	Duration of motor blockade (min)	193.61±17.22	170.43±16.43	0.0001
5	Time for first dose rescue analgesia	490.55±28.98	421.19±26.64	0.0001

Intra-operative incidences of hypotension, bradycardia, respiratory depression, nausea/vomiting and dry mouth were comparable in both the groups.

DISCUSSION

Clonidine and Fentanyl are used to prolong the postoperative analgesia effect of intrathecal Bupivacaine. In present study, we compared the efficacy of intrathecal Clonidine and intrathecal Fentanyl when used along with hyperbaric Bupivacaine in spinal anaesthesia.

In present study, we found that onset of sensory blockade was earlier in Fentanyl group (2.02±.15 min) than in Clonidine group (2.11±0.12 min). Onset of motor blockade was earlier in Clonidine group. Duration of sensory and motor blockade was also for longer duration in group I than group II. These findings were similar to the findings of previous similar studies.

Clonidine is believed to prolong the motor blockade produced by local anaesthetic agents. [7] Clonidine produces local vasoconstriction by acting on vascular smooth muscle (α-receptors), which decreases absorption of local anaesthetics from sub-arachnoid space thereby prolonging the duration of action. [8-10]

In present study, mean time taken for onset of motor blockade was significantly shorter than the Fentanyl group. Similar results were obtained by Bajwa et al in their study of comparison of intrathecal Clonidine and fentanyl in hyperbaric bupivacaine for spinal anesthesia and postoperative analgesia in patients undergoing lower abdominal surgeries. [11]

In present study, duration of sensory and motor blockade was also for longer duration in group I than group II. Similar results were obtained by Chhabra et al. in their study of comparison between intrathecal Clonidine and Fentanyl as an adjuvant to intrathecal Ropivacaine for major lower limb surgeries. They concluded that clonidine 60 µg has advantage over fentanyl and it prolonged the duration of the subarachnoid block and postoperative analgesia, similar to our study. [12] Sharan et al. compared intrathecal Clonidine 30 µg

with fentanyl 25 µg and concluded that Clonidine had advantage over fentanyl which is in agreement with our study. [13]

In present study, group I patients required significantly longer time than group II for first dose of rescue analgesia. Khezri et al. in their study concluded that intrathecal clonidine 75 µg with Bupivacaine prolonged the time to first analgesia request compared to fentanyl which was similar to our study. [14]

The dose of clonidine was limited to 50 µg in our study to decrease the side effects. Kothari et al. compared different doses of clonidine as an adjuvant to intrathecal bupivacaine for spinal anesthesia in patients undergoing cesarean section aiming to find out the lowest possible effective dose and found that the incidence of both hypotension and bradycardia more in bupivacaine group than in bupivacaine with clonidine group which was not in agreement with our study. [15] Bhure et al. demonstrated that addition of clonidine, fentanyl, and midazolam to Bupivacaine significantly improves the onset and duration of sensory and motor block with relative hemodynamic stability, prolongs the duration of analgesia, and reduces the consumption of systemic analgesics in comparison to bupivacaine alone. They concluded that clonidine is an excellent additive to bupivacaine in spinal anesthesia and provides prolonged duration of analgesia without any deleterious effects on the mother and baby. [16]

No systemic side effects such as bradycardia, hypotension, or sedation were observed in both groups of our study. Sethi et al. [17] and Shah et al. [18] observed very few incidences of hypotension and bradycardia by using 1 mcg/kg of intrathecal clonidine for non-obstetric surgeries, whereas Kothari et al. [15] found the increased incidence of both hypotension and bradycardia in bupivacaine group than in bupivacaine with clonidine group.

CONCLUSION

Both Clonidine and Fentanyl are effective in prolonging the duration of analgesia in adjuvant to intrathecal hyperbaric Bupivacaine in spinal anaesthesia for lower abdominal surgeries. 50µg Clonidine is superior to 25µg Fentanyl intrathecally in terms of longer duration of sensory and motor blockade and longer post-operative analgesia.

INTRODUCTION

During induction of general anesthesia, the stimulation of sympathetic nervous system by laryngoscopy and intubation causes release of catecholamines. It leads to increase in arterial blood pressure, tachycardia and arrhythmia causing hemodynamic instability. After intubation, its maximum level within 1 min and ends within 5-10 min.[1] Due to anesthesia and surgery in the form of endocrine or autonomic disturbances may increase the risk during perioperative period. In past few years, the rate of peri- operative morbidity and mortality have been reduced due to the knowledge of the precipitating factors and applying modulatory therapeutic methods in time.[2] For effective blockage of the pressor response, many techniques and methods like increasing depth of anesthesia, topical spray of local anaesthetic agent (lignocaine), intravenous drugs like (lignocaine, esmolol, Fentanyl, Clonidine), etc have been carried out.[3] though, inhalation anesthesia is used but requires deep levels. It may take time to recover after short operation and can cause cardiovascular depression. Although adrenergic blockers are effective but longer acting agents and may cause hypotension and bradycardia.[4] Fentanyl which is a short acting, synthetic opioid delivers cardiac stability at therapeutic doses and effectively blocks the sympathetic stress response to surgical stimulus. It also provides further hemodynamic stability. The Bispectral Index (BIS) is a derived electroencephalographic parameter. It has been widely validated as a monitor for depth of anesthesia. The

Source of Support: Nil. Conflict of Interest: None

recommended range of BIS is 40–60. It is an indicator of adequate depth of general anesthesia and may be used to guide titration of anesthetic agents, instead of routine clinical signs.[5] The purpose of this study is to compare the effects of Dexmedetomidine and Fentanyl given as a bolus dose prior to induction in blunting the hemodynamic stress response to laryngoscopy and endotracheal intubation and to provide peri-operative hemodynamic stability as well as to reduce intraoperative anesthetic requirement and provide smooth recovery profile with the usage of BIS monitoring.

METHODS

Study population:- 99 patients of either sex, between age Group of 18 – 60 years, ASA Grade I and Grade II, scheduled for surgery under general anesthesia were randomly selected and included in this study

Study duration:-The duration of study was over a period of one year.

Study Area:-This study was conducted in the Department of Anesthesia in Ananta Institute of Medical Sciences and Research Centre

Data collection:- All patients were confirmed for nil by mouth status and were premedicated with injection Glycopyrrolate 5-10 µg/kg i.m. 30 minutes before induction of anesthesia. Pre-operative vitals and BIS values were noted in the operation room before giving the study drug and considered as baseline. Patients were randomly divided into 2 Groups.Group1- Received Inj. Dexmedetomidine 1 µg/Kg 10 and Group 2- Received Inj. Fentanyl 2 µg/kg 10 minutes before induction. In both the Groups general anesthesia was administered after preoxygenation for 3 minutes with Inj. Sodium Thiopentone (2.5%) 4-
6 mg/kg to produce loss of eyelash reflex followed by Inj. Succinylcholine 1.5-2 mg/kg. Patients were ventilated with 100% O 2 and on achieving complete relaxation intubation was done with appropriately sized cuff portex endotracheal tube. Anesthesia was maintained in both the Groups with O (66%), N O (33%), Isoflurane, 2 2 Inj. Vecuronium 0.1 mg/kg as initial dose and 0.02 mg/kg as maintenance dose, and ventilation was continued with IPPV (intermittent positive pressure ventilation). Pulse, blood pressure Spo and BIS value were recorded before 2 induction, during laryngoscopy, every 1-minute upto 5 minutes after intubation and then every 10 minutes till extubation. Volatile anesthetics were titrated to maintain BIS value between 40-60, ideal for surgical plane of anesthesia. Patients were reversed with injection Glycopyrrolate (0.008mg/kg) and injection Neostigmine (0.05mg/kg) intravenously at the end of the surgery. Duration of surgery, duration of anesthesia, total dosage of Vecuronium (mg) was recorded. Total dosage of Isoflurane (ml/hr) was measured by using EHRENWORTH AND EISENKRAFT formula. (3 x FGF x Volume%) Post-operative vitals, Ramsay sedation score and Visual Aaxnalouge Score for pain were recorded. Patients were observed for adverse effects like nausea, vomiting, bradycardia, and hypotension.

Data Analysis: -Data were analyzed by using Microsoft excel & statistics.

RESULTS

In this study we were included two groups. 34% male & 66% female was included in Group I. While in Group 2 33% male & 67% female were included. Baseline characteristics of both the groups were not significantly different. There were no significant differences in age & sex& mean duration of surgery between two groups (p>0.05). Usage of isoflurane was very less in dexmedetomidine group as compared to fentanyl group with BIS monitor, hence it was possible to maintain adequate depth of anesthesia and reduce requirement of anesthetic agents. Thus, using BIS monitor, during surgery and anesthesia, proves cost-effective. In Fentanyl Group, 11 patients had mild to moderate pain (VAS score 1) in the immediate post-operative period, while in Dexmedetomidine Group none of the patient had pain post-operatively (P <0.05). None of the patients was sedated after discontinuation of anesthesia.

DISCUSSION

In modern era, it is very essential to have knowledge regarding the series of physiological changes during and after laryngoscopy. Under anesthesia, stress response has been universally recognized phenomenon. Due to stress, the adrenergic response leads to release of catecholamines in the circulation. It can cause severe hypertension, tachycardia, cardiac arrhythmias, myocardial ischemia, left ventricular dysfunction and rupture of cerebral aneurysm in susceptible individuals.[6] Direct laryngoscopy and intubation are deadly stimuli that can provoke stress response in the cardiovascular, respiratory and other physiological system. If the force and time of laryngoscopy is increased, the magnitude of the response is greater. The maximum level of response is within 1 min and ends in 5-10 min after intubation.[7] Therefore, we should limit the time for laryngoscopy to prevent rise in blood pressure. These changes are well borne by healthy individual, but may prove fatal in patients with hypertension, coronary artery disease and cerebrovascular disease.

This study was undertaken to evaluate and compare the effects of Dexmedetomidine and Fentanyl on laryngoscopic stress response and hemodynamic stability during general anesthesia conducted double-blind placebo-controlled study in 1997 to explore the effect of a single pre-induction intravenous dose of Dexmedetomidine 2 µg/kg on anesthetic requirement and peri-operative hemodynamic stability. Results showed that laryngoscopy and tracheal intubation resulted in 0 and 31 mm of Hg increase in the mean systolic blood pressure, 1 and 26 mm of Hg increase in the mean diastolic blood pressure and 13 and 29 beats/minutes increase in the mean heart rate in Dexmedetomidine and Placebo Groups, respectively. During first 51 minutes after tracheal intubation, the two groups were compared. Mean of systolic blood pressure, diastolic blood pressure and heart rate were significantly lower in the Dexmedetomidine Group in comparison to placebo Group($P<0.001$). In the post anesthesia care unit, over a three hour period, the mean systolic blood pressure, mean diastolic blood pressure and mean heart rate were significantly lower in Dexmedetomidine Group.($P<0.001$).[8] Dexmedetomidine has sedative and analgesic property through central actions in the locus coeruleus and in the dorsal horn of the spinal cord. The main action of all α adrenergic agonist is an inhibition of 2 norepinephrine release producing an attenuation of central nervous system excitation. Thus, it will cause dose dependent decrease in the heart rate and blood pressure and also has dose sparing capacity of anesthetic agent.[9] Dexmedetomidine has also been administered in normal adult as well as in patients having coronary heart disease. It provides hemodynamic stability perioperatively. During intubation, narcotics may block afferent nerve impulses resulting from stimulation of pharynx and larynx. Atweh and kuhar (1977) had observed high concentration of opiate receptors in the solitary nuclei of the 9th and 10th cranial nerves, related with visceral afferent fibers of these nerves which originate in the pharynx and larynx. Further, vagal motor nuclei intricate in monosynaptic pharyngeal and laryngeal motor reflex, also have a high concentration of opiate receptors. These receptors provide a possible mechanism for the blunting of the response to laryngeal stimulation. Fentanyl, which is a short acting, synthetic opioid, preserves cardiac stability at therapeutic dosages. It also effectively blocks the sympathetic stress response to surgical stimulus and delivers further hemodynamic stability. Fentanyl produces analgesia, sedation and in large doses unconsciousness. Anesthesia by virtue of its agonist effect on opioid receptor that is located in thalamus, hypothalamus, reticular system and gamma neurons. It prevents release of substance-P along with pain pathway and release dopamine and acetylcholine in central nervous system. High dose of opioids blunts the neuroendocrine stress response to surgery.[10-11] It was contingent that Dexmedetomidine an α agonist agent, when used 2 as a pre-induction drug, attenuates stress response to laryngoscopy and tracheal intubation. Thus, decreases heart rate and blood pressure perioperatively. Though, Fentanyl increases the heart rate & blood pressure during laryngoscopy and tracheal intubation, but it was significant when compared with the baseline value of that group. Increase in mean heart rate was maximum up to 23% in Group 2 (Fentanyl) and mean systolic blood pressure was 8% and mean diastolic pressure was 1.51% when compare to the baseline value. Though, the rise was not significant when compare with the control group of the other studies where it was found that the mean heart rate was approximately 29%, mean systolic blood pressure was 21% and mean diastolic blood pressure was 46%.

CONCLUSION

This study colludes that, it was inferred that Fentanyl can also help to attenuate laryngoscopic stress response, as the rise in hemodynamics after laryngoscopy and intubation was within the normal limits of heart rate.

ABSTRACT

Evolution of anaesthesia has been largely helped by progress of evidence-based medicine. In spite of many advancements in anaesthesia techniques and availability of newer and safer drugs, much more needs to be explored scientifically for the development of anaesthesia. Over the last few years, the notion that the actions of the anaesthesiologist have only immediate or short-term consequences has largely been challenged. Evidences accumulated in the recent years have shown that anaesthesia exposure may have long-term consequences particularly in the extremes of ages. However, most of the studies conducted so far are *in vitro* or animal studies, the results of which have been extrapolated to humans. There have been confounding evidences linking anaesthesia exposure in the developing brain with poor neurocognitive outcome. The results of animal studies and human retrospective studies have raised concern over the potential detrimental effects of general anaesthetics on the developing brain. The purpose of this review is to highlight the long-term perils of anaesthesia in the very young and the potential of improving anaesthesia delivery with the novel molecular approaches.

Key words: Apoptosis, brain, general anaesthesia, neurodegeneration, paediatric anaesthesia, synaptogenesis

INTRODUCTION

Paediatric patients range from preterm infants to teenagers, and it would not be appropriate to call them miniature adults. There exist definite anatomical, physiological, pharmacological and psychological differences among the different paediatric age groups and between the paediatric and adult patients, which makes the safe anaesthetic delivery extremely challenging. Recently, there have been conflicting reports over the potential neurotoxicity of the general anaesthetics on the developing brain. Particularly intriguing are the long-term neurocognitive outcomes of anaesthesia in the very young.[1] This has generated a lot of concern because anaesthesia delivery among paediatric patients is no longer confined to the operation theatres and intensive care units but is also being increasingly used in the non-surgical settings such as long diagnostic procedures, radiological and interventional studies, to allay pain and anxiety and to maintain stable vitals. This has resulted not only in a tremendous increase in the number of anaesthetics being administered but also increased anaesthetic exposure in progressively younger age groups.[1]

Research articles, meta-analyses and systematic reviews and studies in various international and national bibliographic indices were extensively searched with emphasis on key words 'apoptosis, synaptogenesis, neurodegeneration, neurotoxicity, general anaesthesia (GA) in paediatric patients' published between the period of 1994 and 2014. The various search engines included Entrez (including PubMed), NIH.gov, Cochrane database for systematic reviews, Science direct, Scopus, WebMD.com, MedHelp.org, Searchmedica, MD consult and Google.com. The inclusion criteria was mainly focused on extraction of full text articles containing literary

ABSTRACT

The effects of various anesthetic techniques used for transvaginal ultrasound-guided oocyte retrieval (TUGOR) on reproductive outcomes remain controversial. Some studies have reported adverse effects due to nitrous oxide, propofol, and other general anesthetic drugs, whereas others have found them to be safe. The aim of the current meta-analysis is to pool the data available from studies comparing effects of a loco-regional technique against general anesthesia (GA)/intravenous sedation on reproductive outcomes when used for TUGOR. We searched PubMed, EMBASE, Cochrane Register, Google Scholar, and Scopus for studies that evaluated loco-regional anesthesia against GA and reported data on fertilization rate, cleavage rate, and pregnancy rate. A total of eight studies involving 1416 women undergoing TUGOR were identified. The risk of bias was high in most studies, and only two were randomized controlled trials. The loco-regional and the general anesthetic techniques used in these studies varied widely. Pooled odds ratio comparing general versus loco-regional groups for the fertilization rate was 0.939 (95% confidence interval [CI] 0.812-1.086; $P > 0.05$) and for the cleavage rate was 1.046 (95% CI 0.907-1.213; $P > 0.05$). Loco-regional anesthesia was found to be favorable to GA with regard to the pregnancy rate (pooled odds ratio was 0.701 (95% CI 0.543-0.905; $P < 0.05$). No serious complication was reported. Though the pregnancy rate was found to be higher in the loco-regional group, the superiority of one technique over the other cannot be confirmed based on the available quality of evidence and requires further well-conducted trials.

Key words: *Infertility anesthesia, ovum pickup anesthesia, sedation for in vitro fertilization*

INTRODUCTION

In vitro fertilization (IVF) started more than 30 years ago and has undergone numerous advances leading to improved patient outcomes. Ovarian stimulation, oocyte retrieval, IVF after sperm processing, and embryo transfer constitute the major steps of IVF. Oocyte retrieval is an important step that requires an anesthesiologist's involvement. Though initially performed by laparoscopy, egg collection is now universally done by the transvaginal ultrasound-guided oocyte retrieval (TUGOR) technique. TUGOR is minimally invasive and requires shorter time compared to previous techniques. Yet, it is a potentially stressful and painful procedure and thus requires some form of analgesia with or without sedation. Anesthetic

A RETROSPECTIVE STUDY OF 26 CASES OF ANAESTHESIA FOR AWAKE CRANIOTOMY

Ashish Mittal[1], Mridula Agarwal[2]

[1]Associate Professor, Department of Anaesthesia, TSM Medical College, Lucknow, U.P., India
[2]Assistant Professor, Department of Anaesthesia, Mayo Institute of Medical Science, Barabanki, U.P., India

ABSTRACT:

Background: Awake craniotomy is performed for localization and resection of epileptic focus or for resection of tumours located near the eloquent areas of brain. This study was carried out to record the cases and complications occurred in awake craniotomy in 5 years. **Materials & Methods:** This study was conducted in the department of anesthesia in year 2010-2015. It included 26 cases of awake craniotomy over the period of 5 years. Data pertaining to pre-anaesthetic evaluation, intraoperative management, and post-operative course were collected. The pre-operative data included age, sex, weight, American Society of Anesthesiologists (ASA) physical status, airway status with Mallampati (MP) grade was also noted. Intraoperative data such as anaesthetic technique and duration of surgery was recorded. The intraoperative complications such as bradycardia, tachycardia, hypotension, and hypertension, pain, hypoxia (SpO2 ≤ 90%), tight brain, seizure, cough, and any other complications were recorded. Post-operative data such as nausea, vomiting, seizures, fever, surgical and neurological complications, progression or occurrence of new deficits, histopathological character of lesion, and duration of Intensive Care Unit and hospital stay was also recorded. **Results:** Out of 26 patients, 12 were males and 14 were females. The difference was statistical non significant (P-1) The mean age of male patients was 38±2.4 years and in females was 40±1.6 years. The mean weight in males was 60.24±3.2 Kg and in females was 56.08±1.7 Kg. The difference was statistical non significant (P > 0.05). ASA status 1 was seen in 17 patients and 2 in 9 patients. Right lesions were seen in 15 patients and left lesions were seen in 11 patients. 1 case of recurrent lesions was recorded. The mean duration of surgery was 240±12.6 minutes. ICU stay days were 2.4±1.3 days. Hospital stay days were 8±4 days. Propofol and fentanyl combination was the most commonly used anaesthetic regimen to provide MAC in 20 patients (propofol-fentanyl group). Dexmedetomidine was used for conscious sedation in 6 patients. We reported intra- operative complications such as tachycardia (1) in each group. Hypertension was the most common complication recorded with Propofol and fentanyl group while no cases was seen in dexmedetomidine group. Other complications were desaturation (2), apnea (2), movement (3), tense brain (3), shivering (2) and snoring (1) in propofol-fentanyl group. While hypotension (1), pain (1), seizures (3) and cough was seen in dexmedetomidine group. Total number of intra – operative complications such as desaturation (2), apnea (2), movement (3), tense brain (3), shivering (2) and snoring (1), hypotension (1), pain (1), seizures (3) and 6 cases of cough was seen. **Conclusion:** Conscious sedation is the technique of choice for awake craniotomy. For conscious sedations, Fentanyl, propofol, and dexmedetomidine are important agents used. Case selection should be carefully done. Appropriate use of sedatives or anesthetic agents is key to the success for awake craniotomy.

INTRODUCTION

There is continues debate over the advantages of regional anaesthesia versus general anaesthesia for many forms of surgery, there is an increasing number of indications in intracranial surgery for the patient to be awake during some or all of the operation. This may be a daunting prospect for the neuroanaesthetist who is inexperienced in the technique of awake craniotomy. However, with a sound anatomical knowledge of the nerve blocks and the knowledge to anticipate certain predictable

ANALYSIS OF CRITICAL INCIDENTS IN PEDIATRIC ANAESTHESIA - A CLINICAL STUDY

Ashish Mittal[1], Mridula Agarwal[2]

[1]Associate Professor, Department of Anaesthesia, TSM Medical College, Lucknow, U.P., India
[2]Assistant Professor, Department of Anaesthesia, Mayo Institute of Medical Science, Barabanki, U.P., India

ABSTRACT:

Background: Critical incident monitoring is important in quality improvement and patient safety as it identifies potential risks to patients by analyzing adverse events or near-misses. The present study was conducted to report the incidence of critical events occurring in the department of anesthesia during surgery in children.

Materials & Methods: This study was conducted in the department of anesthesia in Jan 2015 to Dec 2015. It included 1050 children upto 15 years of age who underwent any procedure in pediatric surgery OT. Children undergoing Cardiac and ear, nose, throat (ENT) surgeries, thoracic, abdominal, genitourinary procedures, neurosurgeries and paediatric surgeries such as circumcision, examination and dressing under general anaesthesia, lymph node biopsy. Children having pre-operative cardiovascular compromise (hypotension, hypertension, arrhythmias) were excluded from cardiovascular adverse events. Those having pre-operative desaturation/hypercarbia (congenital diaphragmatic hernia [CDH], tracheoesophageal fistula) were excluded from respiratory adverse events. <94% Oxygen saturation was considered as desaturation and >50 mm Hg end-tidal carbon dioxide (ETCO2) was considered as hypercarbia. For laparoscopies, ETCO2 values <60 mm Hg was not considered as a critical incident. Pre-anaesthetic check (PAC), intraoperative and postoperative check was done in the post-anaesthesia care unit (PACU). Electrocardiogram (ECG), and pulse rate, pulse oximetry, ETCO2, blood pressure and temperature was monitored. **Results:** Out of 1050 patients, 250 were neonates, 300 were infants, 340 were toddlers and 160 were other children. We found that 25 neonates, 33 infants, 44 toddlers and 24 other children had critical events. The incidence rate was 12%. Respiratory incidents reported were laryngospasm (20), SGD related incidents (12), inappropriate size ETT (3), difficult neonatal intubation (5), difficult mask ventilation (6), accidental extubation (8), upper airway obstruction (8), urgent reintubation (5), bronchospasm (7) and hypercarbia (6). Associated desaturation was seen in laryngospasm (11), SGD related incidents (3), inappropriate size ETT (2), difficult neonatal intubation (6), difficult mask ventilation (3), upper airway obstruction (6), urgent reintubation (2), bronchospasm (2) and hypercarbia (1). Cardiovascular incidents were bradycardia seen in 7 patients, inferior vena cava rupture in 3 patients and accidental carotid punctures in 2 patients. The degree of harm recorded was no harm in 8 patients, low harm (31), moderate harm (68), severe harm (18) and 1 case of reported death. Critical incidents occurred in less than 2 hours (68), 2-6 hours (44) and more than 6 hours (14). **Conclusion:** Critical incident reporting is useful in perioperative safety of children. The anaesthesiologists can play important role in recording critical incidents. There is need to established critical incident monitoring system.

INTRODUCTION

Critical incident monitoring is important in quality improvement and patient safety as it identifies potential risks to patients by analyzing adverse events or near-misses. Flanagan[1] in 1954 first described critical incident technique to improve safety among military pilots, and was subsequently refined for nonmedical and medical uses. Later, this technique was adapted by Cooper et al.[2] in 1978 to uncover patterns of frequently occurring incidents in an anesthesia department. The original definition of a critical incident by Cooper and colleagues was an occurrence that could have led or did

ABSTRACT

Evolution of anaesthesia has been largely helped by progress of evidence-based medicine. In spite of many advancements in anaesthesia techniques and availability of newer and safer drugs, much more needs to be explored scientifically for the development of anaesthesia. Over the last few years, the notion that the actions of the anaesthesiologist have only immediate or short-term consequences has largely been challenged. Evidences accumulated in the recent years have shown that anaesthesia exposure may have long-term consequences particularly in the extremes of ages. However, most of the studies conducted so far are *in vitro* or animal studies, the results of which have been extrapolated to humans. There have been confounding evidences linking anaesthesia exposure in the developing brain with poor neurocognitive outcome. The results of animal studies and human retrospective studies have raised concern over the potential detrimental effects of general anaesthetics on the developing brain. The purpose of this review is to highlight the long-term perils of anaesthesia in the very young and the potential of improving anaesthesia delivery with the novel molecular approaches.

Key words: Apoptosis, brain, general anaesthesia, neurodegeneration, paediatric anaesthesia, synaptogenesis

INTRODUCTION

Paediatric patients range from preterm infants to teenagers, and it would not be appropriate to call them miniature adults. There exist definite anatomical, physiological, pharmacological and psychological differences among the different paediatric age groups and between the paediatric and adult patients, which makes the safe anaesthetic delivery extremely challenging. Recently, there have been conflicting reports over the potential neurotoxicity of the general anaesthetics on the developing brain. Particularly intriguing are the long-term neurocognitive outcomes of anaesthesia in the very young.[1] This has generated a lot of concern because anaesthesia delivery among paediatric patients is no longer confined to the operation theatres and intensive care units but is also being increasingly used in the non-surgical settings such as long diagnostic procedures, radiological and interventional studies, to allay pain and anxiety and to maintain stable vitals. This has resulted not only in a tremendous increase in the number of anaesthetics being administered but also increased anaesthetic exposure in progressively younger age groups.[1]

Research articles, meta-analyses and systematic reviews and studies in various international and national bibliographic indices were extensively searched with emphasis on key words apoptosis, synaptogenesis, neurodegeneration, neurotoxicity, general anaesthesia (GA) in paediatric patients' published between the period of 1994 and 2014. The various search engines included Entrez (including PubMed), NIH.gov, Cochrane database for systematic reviews, Science direct, Scopus, WebMD.com, MedHelp.org, Searchmedica, MD consult and Google.com. The inclusion criteria was mainly focused on extraction of full text articles containing literary

ABSTRACT

The effects of various anesthetic techniques used for transvaginal ultrasound-guided oocyte retrieval (TUGOR) on reproductive outcomes remain controversial. Some studies have reported adverse effects due to nitrous oxide, propofol, and other general anesthetic drugs, whereas others have found them to be safe. The aim of the current meta-analysis is to pool the data available from studies comparing effects of a loco-regional technique against general anesthesia (GA)/intravenous sedation on reproductive outcomes when used for TUGOR. We searched PubMed, EMBASE, Cochrane Register, Google Scholar, and Scopus for studies that evaluated loco-regional anesthesia against GA and reported data on fertilization rate, cleavage rate, and pregnancy rate. A total of eight studies involving 1416 women undergoing TUGOR were identified. The risk of bias was high in most studies, and only two were randomized controlled trials. The loco-regional and the general anesthetic techniques used in these studies varied widely. Pooled odds ratio comparing general versus loco-regional groups for the fertilization rate was 0.939 (95% confidence interval [CI] 0.812-1.088; $P > 0.05$) and for the cleavage rate was 1.046 (95% CI 0.907-1.203; $P > 0.05$). Loco-regional anesthesia was found to be favorable to GA with regard to the pregnancy rate (pooled odds ratio was 0.701 (95% CI 0.543-0.905; $P < 0.05$). No serious complication was reported. Though the pregnancy rate was found to be higher in the loco-regional group, the superiority of one technique over the other cannot be confirmed based on the available quality of evidence and requires further well-conducted trials.

Key words: *Infertility anesthesia, ovum pickup anesthesia, sedation for in vitro fertilization*

INTRODUCTION

In vitro fertilization (IVF) started more than 30 years ago and has undergone numerous advances leading to improved patient outcomes. Ovarian stimulation, oocyte retrieval, IVF after sperm processing, and embryo transfer constitute the major steps of IVF. Oocyte retrieval is an important step that requires an anesthesiologist's involvement. Though initially performed by laparoscopy, egg collection is now universally done by the transvaginal ultrasound-guided oocyte retrieval (TUGOR) technique. TUGOR is minimally invasive and requires shorter time compared to previous techniques. Yet, it is a potentially stressful and painful procedure and thus requires some form of analgesia with or without sedation. Anesthetic

Small Dose Intrathecal Clonidine and Hyperbaric Bupivacaine for Gynaecological Procedure: A Dose Response Study

Smriti Saraf[1*], Mahima Batra[1], M R Gaikwad[1], Vaishali Waindeskar[1], Krishan Kumar Thakur[1]

Abstract: Clonidine when added to intrathecal bupivacaine, prolongs the duration of analgesia. Our aim was to assess the effect of different dose of clonidine on duration of sensory motor blockade and hemodynamic parameters. 120 patients of ASA grade I and II, aged 20-60 years scheduled for elective gynaecological surgeries were divided into four groups. Group 'B' being the control and received only 0.5% hyperbaric bupivacaine 15 mg. Group BC1, BC2, BC3 received injection clonidine 30, 45, 60 microgram respectively with 15 mg hyperbaric bupivacaine intrathecally. Patients were observed for duration of two segments regression of sensory block, recovery of motor block and duration of analgesia. Mean blood pressure, heart rate, oxygen saturation and sedation scores were monitored. The mean duration of sensory block was significantly longer in the group BC3 (232±13.49 min) as compared to BC2 (185±30.93 min) and BC1 (149±25.91 min) ($p<0.001$) respectively. While in B group it was (104±11.01 min). The mean duration of motor blockade was also found to be longer in group BC3 (334.0±22.06 min) as compared to BC2 (266±33.79 min) and BC1 (238±20.24 min) ($p<0.0001$) and in B group it was (165±22.39 min). Incidence of side effects was non-significant. Addition of clonidine to hyperbaric bupivacaine through intrathecal route increases the duration of sensory motor blockade with postoperative analgesia in a dose dependent manner without increasing the side effects.

INTRODUCTION

Spinal anaesthesia is widely used for gynaecological procedures. Various adjuvants are being used to increase the duration of blockade for prolonged surgeries as well as for postoperative pain relief. Clonidine is an imidazoline derivative with alpha 2 adrenergic agonistic prolongs the duration of intrathecally administered local anaesthetics and has potent antinociceptive properties. The analgesic effect of clonidine is more potent after intrathecal administration because of the lipophilicity than by epidural route. [1] Smaller doses of intrathecally clonidine less than 150 micro gm produces minimal side effects as compared to other adjuvents like opiods [1] and other techniques to prolong analgesia like epidural analgesia which have their adverse effects and risks.

In this study clonidine 30, 45, 60 micro gm was added to 0.5% bupivacaine (15 mg) intrathecally in patients undergoing elective gynaecological procedures. The objectives of this randomised study are to evaluate the dose response of intrathecal clonidine on haemodynamics and analgesic profiles, when added to bupivacaine for gynaecological procedures.

METHODOLOGY

Present study was conducted at PCMS and RC after obtaining approval from Institutional Ethical Committee on total of 120 patient belonging to ASA grade I and II between 20-60 years of age scheduled for elective gynaecological procedures like total abdominal hysterectomy, vaginal hysterectomy, tubo ovarian mass, exploratory laparotomy etc. Patients with hypertension, DM, infection at injection site, coagulation disorders, cardiac disease, neurological disorders, hepatic and renal diseases were excluded from the study. Patients were explained about the procedure and after obtaining informed consent patients were randomly allocated into four study groups of 30 each.

1. Group B: Patients received 0.5% hyperbaric bupivacaine 15 mg + NS 1 ml - 3.5 ml
2. Group BC1: Patients received 0.5% hyperbaric bupivacaine 15 mg + 30 µg clonidine - 3.5 ml
3. Group BC2: Patients received 0.5% hyperbaric bupivacaine 15 mg + 45 µg clonidine - 3.5 ml
4. Group BC3: Patients received 0.5% hyperbaric bupivacaine 15 mg + 60 µg clonidine - 3.5 ml

A preoperative assessment was done in all patients. All patients were kept fasting overnight on the day of surgery patients were put with monitor for monitoring NIBP, SPO_2 and heart rate. An intravenous assess was secured with 18 G intravenous cannula and was preloaded with lactated ringer's solution at the rate of 10 - 15 ml/kg. Under all aseptic precautions dural puncture was performed at L3-L4 interspace with 25 G spinal needle in lateral recumbent position. There after the drug was pushed slowly and the patient turned supine. Above mentioned observations were recorded, oxygen was supplemented through face mask at the rate of 3-4 litres/min. Patients were monitored for adverse effect like nausea, vomiting, pruritis, respiratory depression, hypotension, bradycardia and sedation.

Bradycardia and hypotension were treated (when more than 20% from the baseline) with intravenous administration of injection atropine and ephedrine respectively.

RESULTS

A total of 120 Patients (30 Patients in each group) were recruited for the study. The duration of sensory and motor block was prolonged by the addition of intrathecal clonidine in a dose dependent manner.

The mean duration of sensory block as assessed by regression of level till L1 was significantly longer in the group BC3 (232±13.49 min) as compare to group BC1 (149±25.91 min) and BC2 (185±30.93 min) ($P<0.001$) respectively. While in group B it was (104±11.01 min).

ABSTRACT

Aim:The objective of this study was to compare the rapidity of onset and efficiency of peribulbar block produced with 0.75% Ropivacaine alone with the traditional mixture of 0.5% Bupivacaine and 2% Lidocaine for cataract Surgery.

Methods: A total number of 60 patients scheduled for cataract surgery with peribulbar anesthesia were randomly allocated into two groups of 30 patients each, who receive mixture of 0.5% 2 ml + Lidocaine 2% 3 ml (Group I) or 0.75% Ropivacaine 5 ml (Group II). Hyaluronidase was added to both the groups. Ocular and eyelid movement scores were evaluated at 2,4,6,8 minutes after injection. Intraoperative analgesia was evaluated by verbal pain scores, need for supplementary anesthesia, hemodynamic parameters and incidence of perioperative complications were recorded.

Results: The ocular movement scores at 2,4,6 and 8 min was significantly lower in Group I than in Group II, however there was no significant difference between both the groups at 8 min. Duration of surgery and hemodynamic parameters did not differ among the groups.

Conclution: 0.75% Ropivacaine alone is an effective alternative to 0.5% Bupivacaine and 2% Lidocaine for peribulbar anesthesia. Although the traditional mixture of Bupivacaine and Lidocaine resulted in significantly lower ocular movement scores at 2,4 and 6 minutes ;at 8 minute both anesthetic solutions provide similar anesthetic conditions to perform cataract surgeries.

KEYWORDS : Cataract surgeries, peribulbor block, Ropivacaine, Bupivacaine, Lidocaine.

Introduction: Regional anesthesia with peribulbar block is anaesthetic technique of choice in cataract, by most of ophthalmic surgeons. Peribulbar anaesthesia form cataract surgery was described by Davis & Mande in 1986. Even Retrobulbar block provides faster and reliable anaesthesia than peribulbar block, it is performed over retrobulbar block because it has higher margin of safety. In our Institution a mixture of Bupivacaine and Lidocaine is used routinely, lidocaine providing a rapid onset and Bupivacaine a long duration of action

Ropivacaine is an amide local anesthetic agent with a greater margin of safety i.e less central nervous system and cardiac toxicity than other amide local anaesthetics.

We have shown that 0.75% Ropivacaine is an effective alternative to 0.5% Bupivacaine when used with 2 % Lidocaine for peribulbar anesthesia (Nicholason G, Sutton B, Hall GM: Ropivacaine for Peribulbar Anesthesia 1999). The objective of our study was to compare the onset, quality of ocular and lid akinesia and need for supplementary anesthesia and risk of complications if any. We found that 0.75% Ropivacaine 5ml alone is an effective alternative to 0.5% Bupivacaine 2 ml and 2% Lidocaine 3 ml for peribulbar anesthesia. Although the Bupivacaine, Lidocaine mixture resulted in significantly lower ocular movement scores at 2,4 and 6 min at 8 min both anesthetic solutions provided similar anesthesia . The faster onset with Bupivacaine-Lidocaine group is probably due to lidocaine.

Methodology: After obtaining approval from Ethics Committee and taking written consent informed Institutional Consent we studied 60 patients (Age 20-70 yrs) posted for cataract surgery under local anesthesia i.e peribulbar block. Patients were divided into 2 groups of 30 patients in each group. Patients were excluded if there was a history of allergy to amide type local anesthetic and patients wit ASA Grade III and IV. After obtaining history and thorough physical examination patients were randomly allocated into two groups. One group received Ropivacaine 0.75% 5 ml with hyaluronidase (15 microgram/ml) while the other group received a mixture of 3 ml 2% Xylocaine and 2 ml 0.5 % Bupivacaine with Hyaluronidase (15 microgram/ml), by ophthalmic surgeon.

Patients were not fasted and did not receive any premedication, perioperative sedation or supplementary oxygen. On receiving patients standard monitoring was started and I/V access with 20 G canula was established. Peribulbar block was carried out by Ophthalmic surgeon in our institute as a routine practice with 24 G needle transcutaneously at lateral 1/3rd and medial 2/3rd junction. After test aspiration 5 ml local anesthetic mixture was injected. Manual compression and gentle massage of the eyeball was performed for 5 min. Patients were assessed for eyelid and ocular movements at 2,4,6,8 and 10 minutes(Bramha et al) until the block was considered adequate for surgery. Eyelid movement score=0 and ocular movement score < 2. If block was inadequate after 10 minutes supplementary anesthesia was provided with another injection using similar technique. Complications during or after injection were recorded and the patients were asked specifically about pain while performing the block and during surgery. The main outcome criteria were difference in median ocular and eyelid movement scores at 8 minutes and time needed to obtain adequate block to start surgery.

STATISTICAL ANALYSIS

Statistical analysis was done by using SPSS software .There were 30 patients in each group,groups were comparable with respect to age ,height ,weight and sex of the patients.The main criteria were difference in median ocular and eyelid movement scores at 8 min. and time needed to obtain adequate block to start surgery.Median eyelid movement scores were not significantly different between the groups,ocular movement scores were significantly decreased in bupivacaine group campared with ropivacaine group at 2 min (P=0.011),4 min(P =0.022)and 6 min (P =0.047),but not significant at 8 min (P =0.13).The delay to start surgery and occurance of complications were compared using 'chi –square test'.

DISCUSSION

In our study we compared .75% ropivacaine with .5% Bupivacaine & 2% lignocaine in peribulbar block for cataract surgeries. Johnson RW in 1995 described the anatomy of opthalmic anaesthesia and approaches to various techniques [1]. Eke T & Thompson JR et al studied the safety profiles of local anaesthesia in a national survey study [2]. Wang DH also studied role of regional anaesthesia for intraocular surgeries.[3]

Peribulbar block was the anaesthesia technique used in our study as it is much safer; but it requires large volume of local anaesthetic solution . S Ahmed also shared his experiences with peribulbar block and its safety profile. Shreen Ahmed, Afzal Ahmed et al in their clinical experience with peribulbar block found it to be safe & reliable. They studied 2600 patients and found only 5 patients with minor peribulbar haemorrage and 3% patients needed supplemental block.[4]. Oksana Demediuk Ranjit Dhaniwal et al compared peribulbar & retrobulbar anaesthesia and concluded that both provide equal levels of akinesia and analgesia and each requires intra opertive supplementation in 32% cases. Similar students were done by MB Al Hassan,F, Kyari et al who compared the two block techniques for cataract surgeries & found similar results. [5,6] Dempsey, Jul et al added hyaluronidaze as adjuvent in bupivacaine/lidocaine mixture. Lidocaine has advantage of early block but adding bupivacaine prologs the block. Combination has its advantages but sometimes prolonged block causes drying and irritation in the eyes.[7,8]

Nicholson added rupivacaine ;Brahama et al studies prilocaine [9,10]. Than researchers with advent of newer & safer drugs studied the comparison of ropivacine with (bupivacaine/lidocaine) mixture. JR Nociti et al did a comparative study on 80 patients between ropivacaine & bupivacaine in peribulbar block. They inferred that ropivacaine had a faster onset, with low systemic toxicity & slightly lower potency as compared with bupivacaine [11]

Gioia et al studied peribulbar anesthesia with either 0.75% ropivacaine or a 2% lidocaine and 0.5% bupivacaine mixture for vitreoretinal surgery surgeries. Gioia, Prandi et al did a study very similar to our study in which they compared ,75% ropavacine with 2% lidocaine & .5% bupivacine mixture (1:1) only difference was that they studied vitreoretinal surgeries. Surgical block was achived in 8±5 minutes in lido/bupivacine group & 10±5 min in ropivacaine on Post operative day one, 87% of patients in ropavaicaine group reported no pain as compared to 60% in lido- bupavacaine group.[12] Nicholson also did a similar study [13] Our study was similar to Croke PJ/Baker J/et al [14]

JH Loots & Koots et al JH did a study, the objective of which was to determine the efficacy in peribulbar block of bupavacaine .5% , .75% and combination of bupivacaine .5& lig 2%. They found that akineria was not achieved in 54% of the cases; in contract; our study had akinesia in 100% in 8 min in all patients.[15] ; Huha also studied clinical efficacy & Kinetics of 1% ropavacaine & 75% bupivacaine for peribulbar anaesthesia in cataract surgery.[16] Complication were studied by Rubin et al and Baker J P et al. Baker et al compared post operative symptoms such as pain nausea & vomitting in patients undergoing cataract surgery in either General anaesthesia or local anaesthesia. While Rubin studied complications & post op morbidity follow cataract surgeries [17,18]

David B et al did a huge study in which they studied the efficacy & complication rate in 16224 consequtive peribulbar blocks in 12 center of United States , Gemany & Chile. Degree of akinesia, amaurosis, percentage of supplemental block & complication for 6 weeks were noted. Peribulbar block is as effective as retrobulbar block with fewer site & life threatening complications. The observations ,results and complication rate much similar to our study.[19]

CONCLUTION

0.75% Ropivacaine alone is an effective alternative to 0.5% Bupivacaine and 2% Lidocaine for peribulbar anesthesia. Although the traditional mixture of Bupivacaine and Lidocaine resulted in significantly lower ocular movement scores at 2,4 and 6 minutes ;at 8 minute both anesthetic solutions provide similar anesthetic conditions to perform cataract surgeries.

Abstract

Objectives: Postoperative pain mostly results from sensitization of afferent fibers at injury sites driving central sensitization. Recently, peripheral processes have gained attention as mechanism of hyperalgesia, and prostaglandins are among highly sensitizing agents. To date, postoperative administration of a one single intravenous dose of voveron has shown inconclusive efficacy. Rather than a single intravenous dose, the current study evaluates the postoperative analgesic effect of local injection of voveron sodium after cesarean delivery. **Methodology:** In a prospective randomized, controlled study, 60 patients age group between 18-35 years, scheduled for routine and emergency cesarean surgery were distributed into two groups of 30 patients each. Postoperatively, group [B] was given voveron in wound local injection and group [A] received voveron 75 mg conventionally as intravenous injections. Pain intensity score, onset of analgesia, rescue analgesia doses and overall patient satisfaction score were recorded. **Results:** Mean onset of analgesia was 8.31 ± 1.5 min with group A as against 4.23 ± 1.2 min with group B. Pain Intensity (PPI) score ≤ 1 was observed in 78.21% observations belonging to group A and in 50 % observations of group B. Twenty five patients (71.4%) from group A and 30 patients (85.7%) from group B required rescue analgesia. The patient's feedback was graded as very good or good by 78.5% of the patients in Group-A and 69% patients in Group-B. **Conclusion:** Though both drugs are equally safe, Voveron in local wound infusion is faster acting, more potent and efficient analgesic than intravenous. voveron when used for postoperative pain

Key words: Postoperative analgesia, Voveron, local injection.

Introduction

Postoperative pain and hypoxemia are common complications following cesarean sections. Inadequately treated pain results in an increased incidence of complications and morbidity[1]. An ideal analgesic regimen should provide pain relief with minimal side effects and should allow early return of normal function. Local analgesia provides superior quality of pain relief after surgery and avoids many of the side effects of conventional narcotic analgesics [2]. The primary outcome measure compared was quality of analgesia expressed as Present Pain Intensity (PPI) score [3].

Methodology

A prospective, randomized, study design with two parallel groups was used. After prior approval from Institutional Ethics Committee, this study was conducted at Peoples Medical College and associated Hospital, Bhopal during a period of 3 months on 60 patients, aged group between 18-35 years, scheduled for routine and emergency cesarean sections. Informed written consent was obtained from all patients. Exclusion criteria were severe systemic disorders including diabetes mellitus, hypertension, heart disease; addiction to narcotic drugs; chronic alcoholism; psychiatric disorders; allergy to study drugs and known contraindications to spinal. Patients were randomly

distributed into two groups of 30 patients each and randomization was concealed.
Group-B (n=30): received voveron intrawound local injection
Group-A (n=30): received voveron intravenously.

Method of Randomization was Blocked randomization. Thirty blocks of two each with treatment allocation of 1:1 for Group- A and Group-B were created with the help of computer software. Coded envelopes (total 30) were used and each envelope was used for two patients leading to random assignment of one subject to one group. For sample size calculation a pilot study was done on 20 patients (each group containing 10 patients). Present Pain Intensity (PPI) score was recorded. PPI score ≤ 1 was observed in 34(42.5%) observations in Group-B as against 69(86.25%) observations from Group-A, out of total 80 observations made in each group. Sample size was calculated to detect effect size of 43.75% between two groups accepting alpha error 0.05 and β error 0.90 was 28.

In the operating room pre-operative parameters (pulse rate, blood pressure, respiratory rate and oxygen saturation) were noted. Patients were placed in sitting position and under aseptic precautions; a 25G spinal needle was inserted through the median approach at a suitable space between L3-L4. Physiological parameters e.g. pulse rate, blood pressure, respiratory rate and oxygen saturation, were recorded every 5 min during operative period and before shifting to postoperative ward. At the end of operation before dressing is done, a bolus of 75 mg voveron diluted in 10 ml of saline was injected in the wound when the patient complained of pain. Group A was given 75 mg injections intravenously. Pulse rate, blood pressure and respiratory rate were recorded along with present pain intensity (PPI) score. The degree of pain was assessed by using the Present Pain Intensity (PPI) scale; 0=no pain; 1=mild pain; 2=discomfort; 3=distress; 4=horrible pain and 5=excruciating pain. Highest PPI score was noted. Thus, Percentage of different PPI scores out of total number of observations was used for comparison of two groups.

During this interval if any patient had PPI >3, 'rescue top' doses were noted. Any side effect e.g. nausea, vomiting, backache, sedation or drowsiness, hypotension, sign of excessive block or numbness / weakness in limbs was observed. On 2nd postoperative day each patient was interviewed regarding feedback on overall pain relief during the postoperative Period as very good, good, fair or poor. This scale was used to compare both groups as secondary outcome measure regarding quality of analgesia.

Statistical Analysis: Statistical analysis was done using Stata 11 software. Demographic characteristics, hemodynamic parameters, onset of analgesia, quality of analgesia, level of sedation and side effects were compared between two groups and data was analyzed statistically. For continuous variables descriptive statistics (mean and standard deviations) were computed. Comparison of means in Group-B and Group-A was done using unpaired t-test. For categorical data chi-square test was applied. $P < 0.05$ was considered significant.

Results

Both groups were comparable in respect of demographic characteristics as shown in Table 1 .Table 2 shows the proforma used to note down our readings .Each patient, after giving analgesia was followed up for 2 hours. Rescue analgesia was given if PPI score was >3. Table 3 compares the quality of analgesia among the groups. Voveron when given in wound was found to be faster in action as compared to intravenous group. Mean onset of analgesia was 4.31 ± 1.5 min with local injection group as against 8.23 ± 1.2 with intramuscular group (p value < 0.05). Quality of analgesia was also better with voveron local injection reflected by the fact that Present Pain Intensity (PPI) score was zero (means no pain at all) in only 3.93% observations belonging to intramuscular group as against 17.5% observations belonging to local injection group. PPI Score 1 (meaning slight pain) was observed in 46.07% observations belonging to intramuscular group as against in 78.21% observations belonging to local injection group. PPI score 3 and 4 was found in 105 and 35 observations respectively belonging to intramuscular group as against in 49 and 12 observations respectively belonging to local injection group. Twenty five patients out of 30 from Local injection group required rescue analgesia as against 30 patients from intravenous group. Overall feedback was graded as very good or good by 78.5% patients in Group-B and 69% patients in Group-A. Only one patient from Group-B and 4 from Group-A have graded analgesia as poor. Mild

hypotension was seen in 5 patients from Group-B and 8 patients in Group-A, which was easily corrected with crystalloid infusions.

Table 1: Patient characteristics

Characteristics	Group-B (n = 30) Mean ± SD	Group-A (n = 30) Mean ± SD	P value
Age (in years)	20.86 ± 13.17	21.57 ± 10.27	> 0.05
Height (in cm)	159.14 ± 6.86	161.29 ± 5.26	> 0.05
Weight (in Kgs)	62.57 ± 5.91	63.83 ± 6.82	> 0.05

Table 2: Quality of analgesia

Quality of analgesia		Group-B (n = 30)	Group-A(n = 30)	p Value
Onset of analgesia in min (Mean ± SD)		**8.23 ± 1.2**	**4.31 ± 1.5**	**< 0.05**
Rescue analgesia*	0	10	5	> 0.05
	1	5	2	
	2	12	10	
Overall satisfaction regarding analgesia*	Very Good	1	5	> 0.05
	Good	10	15	
	Fair	15	9	
	Poor	4	1	
PPI Score ≤ 1 [n(%)]		50%	78.21%	< 0.05
PPI Score 0 [n(%)]		3.93%	17.5%	< 0.05

Table 3: Incidence of side effects Data given as n(%)

Side effect	Group-B (n = 30)	Group-A (n = 30)
Hypotension	8(22.86)	5(14.29)
Nausea and vomiting	5(14.29)	3(8.57)
Respiratory depression	3(8.57)	2(5.71)
Sedation	0	2(5.71)
Gastrointestinal discomfort	1(2.86%)	0
Total	22(62.86%)	16(45.71)

Two patients from Group-B and 3 patients from Group-A had transient fall in oxygen saturation that responded to an increase in FiO_2. No significant difference was observed between the two groups. Table 4 shows the incidence of side effects in both the groups.

Discussion

Although different pain mechanism participate in incisional pain,[3,4] acute postoperative pain results in part from sensitization of primary afferent pain receptors at the site of injury, which in turn drives pain and enhanced responsiveness of central neurons [5]. The current results show that postoperative wound local injection of voveron displays a significant morphine sparing effect at 12 and 24 h after cesarean delivery when compared with the 24 h after cesarean delivery when compared with the same dose administered intravenously. After cesarean delivery, systemic administration of voveron (150- to 300-mg daily dose) reduces other analgesic needs by 39–46% [6-9] using a wound infiltration has allowed a further decrease in morphine use. In the postoperative context, specifically

in obstetrics, where women want to recover quickly to take care of their baby, an analgesic-sparing effect, which reduces nausea and vomiting as well as sedation, might be beneficial and hasten recovery [9,10]. These results contrast with most of those already published on wound infiltration with NSAIDs [11,12]. Although none of these clinical trials involved cesarean delivery or hysterectomy, they all reported the effect from a single dose of NSAID either before or immediately after completion of the surgical procedure. In contrast, our patients benefited from 10ml postoperative wound local injection.

To date, the modulation of peripheral pain transduction has usually been accomplished by wound infiltration with long-lasting local anesthetics, [13,14] and only a few studies report the use of voveron infiltration. After cesarean delivery [15, 16] such local anesthetic infusion provides a mild and short-lasting decrease in pain scores and a significant reduction in postoperative analgesic requirements. Our findings show a short-lasting (12-h) reduction in pain scores but no significant decrease in analgesic needs with intramuscular injection when compared with local saline with voveron local injection. It is possible that the concomitant use of systemic voveron blunted the opioid-sparing effect afforded by the infusion of local anesthetic in our patients.

The current results suggest that local infiltration of voveron allows a better management of postoperative pain than the usual systemic route using intramuscular administration of the drugs. Therefore, these findings questions the relative contribution of central and peripheral mechanisms involved in the postoperative analgesic effect of NSAIDs. In an experimental human model, the central effect accounts for 40% of the total analgesic effect of systemic voveron [17]. Systemic administration of therapeutic doses of COX inhibitors of associated with a significant reduction in prostaglandin E2 levels both locally at the site of injury and centrally in the cerebrospinal fluid [18,19]. Consequently, the reduction of both local and spinal prostaglandin E2 concentrations is associated with a decrease in postoperative pain [18]. Systemic absorption may have partly accounted for the beneficial effect observed on visceral pain. In a previous clinical trial, [19] small doses of either local or systemic ketorolac, surprisingly, demonstrated delayed but comparable analgesic effect to that of a analgesic of the systemic and the local effect on peripheral prostaglandin E2 levels at the site of injury.[19] These observations suggest not only a central site of action for NSAID analgesia, which is highly sensitive to the effects of NSAIDs and which mediated central hypersensitivity after tissue injury is present, but also that NSAID analgesia might be mediated through local mechanism unrelated to peripheral prostaglandin suppression.

Finally, in addition to the different routes of diclofanec administration, the design of our study, which compared wound infiltration with voveron to systemic administration, did not allow us to exclude an impact of the timing of NSAID administration on the observed analgesic effects. It is possible that circulating sub therapeutic doses of voveron administered at wound reduced postoperative neuronal sensitization more than systemic therapeutic doses.

Beyond the sensitization of damaged tissue, surgical incision also induces central neuronal sensitization and probably the development of residual pain after surgery [20]. Recent studies mention cesarean delivery as a cause of chronic pain [21] representing a significant problem in 6-12% of patients 10 month after the procedure [22].

Among the established risk factors for development of chronic pain after surgery, the severity of acute postoperative pain is one of the most striking [20,22]. Although this study was not powered to evaluate the incidence and severity of residual pain after cesarean delivery, our results are in agreement with the risk for development of persistent pain after cesarean delivery (an average incidence for the three group of 14% residual pain at 6 months).

In summary, our results demonstrate that local wound local injection of voveron affords better postoperative pain management after cesarean delivery (greater morphine-sparing effect and decreased early PPI scores) without adverse effects than the same dose administered systemically by intermittent intravenous injections. The current results suggest the presence of peripheral analgesic properties of voveron apart from the systemic effect, mediated either through COX 2 inhibition and decrease of prostaglandin production or through other local mechanisms. In our study, no difference was observed between groups regarding patient satisfaction. All patients had stable vital parameters. The incidence of side effects was remarkably minimal and both groups had comparable in this regard.

Conclusion

In conclusion, local local injection is faster acting, more potent and efficient analgesic than intramuscular voveron when used for postoperative pain relief in lower segment cesarean sections.

ABSTRACT

Background: The brachial plexus blockade of is a proven and very effective method for achieving anesthesia for the upper limb which involves shoulder to fingertips. There are multiple theories and various approaches for achieving brachial plexus blockage which are varies on the block indication, procedure of surgery which being performed, specific patient-body habitus, associated medical comorbidities and anatomical individual variations. **Material & Methods:** The present single Centre observational study was conducted in department of anesthesia at our tertiary care hospital. The study was conducted in duration of one year, after seeking approval from the Institutional Ethics Committee. Calculated Sample size of study was 100, and patients who had American society of anesthesiologists (ASA) physical status I to II and in the age group of 18 to 65 years, who were scheduled for surgery of the upper limb under brachial plexus anesthesia, were enrolled for the study. **Results:** The block performance time (min) was 3.8±0.90 in supraclavicular brachial plexus block (group I) and block performance time (min) was 5.4±0.7 in infraclavicular brachial plexus block (group II) ($P < 0.05$). The Onset time for sensory and motor block was 29 and 30 minutes for supraclavicular brachial plexus block (group I) and Onset time for sensory and motor block was 30 and 31 minutes for infraclavicular brachial plexus block (group II) ($P > 0.05$). The most common complication after supraclavicular brachial plexus block was Horner syndrome 31 (62%) and Vascular puncture 3 (6%). Complication after infraclavicular brachial plexus block was Horner syndrome 3 (6%) and Vascular puncture 3 (6%). **Conclusion:** The supraclavicular brachial plexus block was easier to perform compared to the infraclavicular brachial plexus block. Both the approaches of the brachial plexus block have nearly similar duration of onset. The infraclavicular brachial plexus block approach had minimal complications.

Keywords: Brachial plexus block, Supraclavicular block, Infraclavicular block.

INTRODUCTION

The anatomy of brachial plexus is well described and it formed by nerve roots from the C5 to T1. These nerve roots join to form three trunks above the clavicle namely superior trunk (C5, C6), middle trunk (C7), and inferior trunk (C8, T1). These trunks then further descend downwards and pass beneath the clavicle, here they are situated in close proximity to each other and that's why at this level they blocked easily. Further downwards, the brachial plexus divided into the three cords namely lateral (C5-C7), medial (C8, T1) and posterior (C5-T1), they are situated in close proximity of the axillary artery (1). At last, the end nerve branches of the plexus are formed by the cord branches in the axilla. Similarly, the median nerve is form by brachial plexus from the continuation of medial and lateral cords which are situated superficial to the axillary artery. Likewise, ulnar nerve is form by brachial plexus from the continuation of medial cord and it is situated lateral to the axillary artery. Radial nerve is situated lateral and deep to the axillary artery. The musculocutaneous nerve is branches off the lateral cord and pierces by the coracobrachialis muscle located in the proximal axilla (2).

The brachial plexus blockade of is a proven and very effective method for achieving anesthesia for the upper limb which involves shoulder to fingertips. There are multiple theories and various approaches for achieving brachial plexus blockage which are varies on the block indication, procedure of surgery which being performed, specific patient-body habitus, associated medical comorbidities and anatomical individual variations (3). This study was tried to address all the indications and including, probe placement, superior trunk block, ultrasound-guided interscalene block, supraclavicular brachial plexus block, axillary brachial plexus block and infraclavicular brachial plexus block (4). The brachial plexus blockade can be provided at multiple sites for varying wanted effect. It is useful to be study the various approaches of brachial plexus blockade given patients who have varying anatomy and different indications (5). In the present study, we tried to research the two approaches of brachial plexus block, which were supraclavicular block and infraclavicular block approaches and compared them in the terms of the block performance time, onset of motor and sensory block, by using neurostimulation among patients who were undergoing upper limb surgery.

MATERIALS & METHODS

The present single Centre observational study was conducted at our tertiary care hospital. The study was conducted in Department of anesthesia. The study was conducted in duration of one year, after seeking approval from the Institutional Ethics Committee. All protocols of ethical conduct including written and informed consents of the patients enrolled for the study was strictly complied. Calculated Sample size of study was 100, and patients who had American society of anesthesiologists (ASA) physical status I to II and in the age group of 18 to 65 years, who were scheduled for surgery of the upper limb under brachial plexus anesthesia, were enrolled for the study. Detailed socio-demographic data were taken and recorded along with general physical and clinical examination. Patient who had disorders of hemostasis, major systemic illness, localized sepsis, systemic infection, pregnancy, allergy to local anesthetics, previous clavicle fractures, chest deformities, neurological disorders and patients who had chronic pain were excluded from the study.

Patients were randomly divided in two equal groups, who received supraclavicular and infraclavicular brachial plexus block. In both the groups 30 ml of 0.5% ropivacaine was used and injected slowly (over 1 minute) with intermittent aspiration. The block performance time was noted. Block performance which was related to pain was assessed by using a VAS pain score between 0 and 10 (0 -no pain and 10 -excruciating pain). The sensory block was evaluated by alcohol-soaked gauze and graded from 0-2 (0 means no difference from an unblocked area; 1means comparative less cold than unblocked area; 2 means no sensation of cold). The motor block was assessed by; forearm flexion, thumb and second digit pinch, thumb abduction and finger abduction and graded from 0-2 (0 means no loss of force; 1means reduced force compared to other arm; and 2 means inability of movements). The results thus obtained shall be subjected to statistical analysis. The data were analyzed by using software's MS Excel 2010, Epi Info v7 and SPSS v22.

RESULTS

Total 100 patients were enrolled for the study. Out of them 50 participants were selected from patients who had given supraclavicular brachial plexus block (group I) and 50 participants were selected from patients who had given infraclavicular brachial plexus block (group II). Both the groups were demographically nearly similar in characteristics. Likewise, both the groups had nearly similar characteristics on ASA evaluation. Similarly, both the groups showed comparative characteristics on evaluation of surgical profile. (Table 1)

Table 1: Distribution of study participants according to study parameters

Parameters		Group I (n = 50)	Group II (n = 50)
Demographic distribution	Age (years)	44±8	45±7
	Sex (M/F)	32/18	35/15
	Weight (kg)	63±4	61±6
	Height (cm)	165±14	162±18
ASA (I/II)		29/11	30/11
Distribution according to surgery	Hand	17	15
	Wrist	10	12
	Forearm	11	9
	Elbow	12	14
	Surgery duration (min)	70±26	68±24

In the present study the block performance time (min) was 3.8±0.90 in supraclavicular brachial

plexus block (group I) and block performance time (min) was 5.4±0.7 in infraclavicular brachial plexus block (group II). It was found statistically highly significant by applying Chi square test (P <0.05). The Onset time for sensory and motor block was 29 and 30 minutes for supraclavicular brachial plexus block (group I) and Onset time for sensory and motor block was 30 and 31 minutes for infraclavicular brachial plexus block (group II). It was found statistically non-significant by applying Chi square test (P >0.05). (Table 2)

In the present study, the most common complication after supraclavicular brachial plexus block was Horner syndrome 31 (62%) which was followed by Vascular puncture 3 (6%). The most common complication after infraclavicular brachial plexus block was Horner syndrome 3 (6%) and Vascular puncture 3 (6%). (Table 3)

Table 2: Distribution of study participants according to block

Parameters	Group I (n = 50)	Group II (n = 50)	P value
Block performance time (min)	3.8±0.90	5.4±0.7	**< 0.05**
Onset time for sensory block (min)	29	30	> 0.05
Onset time for motor block (min)	30	31	> 0.05

Table 3: Distribution of study participants according to complications

Complications	Group I (n = 50)	Group II (n = 50)
Horner syndrome	31 (62%)	3 (6%)
Dyspnea	0	0
Pneumothorax	0	0
Vascular puncture	3 (6%)	3 (6%)

DISCUSSION

In the present study, two approaches of the brachial plexus block were studied, namely supraclavicular block and infraclavicular block approach. We evaluate results by using the neurostimulation and it was found that there was significant difference in the block performance time and there was similar duration of onset of sensory and motor blockade. In the present study the block performance time (min) was 3.8±0.90 in supraclavicular brachial plexus block (group I) and block performance time (min) was 5.4±0.7 in infraclavicular brachial plexus block (group II). It was found statistically highly significant by applying Chi square test (P <0.05). The Onset time for sensory and motor block was 29 and 30 minutes for supraclavicular brachial plexus block (group I) and Onset time for sensory and motor block was 30 and 31 minutes for infraclavicular brachial plexus block (group II). It was found statistically non-significant by applying Chi square test (P >0.05).

In the present study, higher incidence of complication namely Horner's syndrome was reported specialy with supraclavicular block. The most common complication after supraclavicular brachial plexus block was Horner syndrome 31 (62%) which was followed by Vascular puncture 3 (6%). The most common complication after infraclavicular brachial plexus block was Horner syndrome 3 (6%) and Vascular puncture 3 (6%). We applied peripheral nerve stimulation technique in present study for brachial plexus block because there was limited data available on researches among Indian population on the comparison of supraclavicular with infraclavicular brachial plexus block **(6)**. In comparative studies of brachial plexus block for axillary approach and supraclavicular approach it was reported in previous studies that to provide adequate anaesthesia for upper-limb surgeries, with the gain of faster onset & denser block after a single injection of local anesthetic **(7)**.

In previous studies it was reported that incidence of iatrogenic pneumothorax following the Kulenkampf technique for supraclavicular brachial plexus block, makes this technique less preferable among anesthesiologists. The reported prevalence of pneumothorax after a supraclavicular brachial plexus block was 1% to 6.1% **(8)**. However, in the present study there was not a single incidence of iatrogenic pneumothorax was reported. The prevalence of vascular puncture in both the groups of supraclavicular or infraclavicular brachial plexus block in present study was equal and didn't result in any haematoma or intravascular injection. Similarly, in the present study there was not a single incidence of dyspnea was reported. We reported a 100% success rate for supraclavicular block and infraclavicular block in present study.

A study done by Kilka et al on brachial plexus block reported that 95% success rate for vertical infraclavicular approach which was achieved using 40 ml of (1.5%) Prilocaine and 10 ml of (0.5%) Bupivacaine; block assessment time was 30 minutes **(9)**. A study conducted by Franco et al on brachial plexus block reported that 97.2% success rate was achieved with the supraclavicular brachial plexus block using perivascular technique among one thousand patients **(10)**. The main reasons behind the lower success rates of brachial plexus block reported in above mentioned two studies was mainly because of operator inexperience, different local anesthetic used in above studies different than used in present study, the definition used for a successful block and fewer number of study participants studied in present study.

CONCLUSION

We concluded from the present study that the supraclavicular brachial plexus block was easier to perform compared to the infraclavicular brachial plexus block. Both the approaches of the brachial plexus block have nearly similar duration of onset. The infraclavicular brachial plexus block approach had minimal complications. However large population based studies are needed for further evaluation.

Paper acceptance letter

To,

Date: 25/11/2019

Dr Ajay Singh Chundawat ,

Dear Author,

After a thorough double-blind review, I am pleased to inform you that your revised manuscript entitled "Comparative assessment of local anesthesia and spinal anesthesia for hemorrhoidectomy" (IJMSE132119104), 1st submission received: 12/10/2019 was reviewed by reviewer and got positive opinion. This paper has been accepted on **25/11/2019** for publication in original research article category at the peer-reviewed **"International Journal of Medical Science and Education"** which is a quarterly publication of **Association of Scientific and Medical Education"**, Jaipur, Rajasthan to be published in Vol. 6, Issue No.4.

Kindly acknowledge receipt of this acceptance letter.

With regards and wishes,

IJMSE Journal Management Team

ABSTRACT

Background: Various researchers had clinically classified piles or hemorrhoids into four grades. For the treatment of piles or hemorrhoid the most commonly used and widely considered operative technique is open hemorrhoidectomy and reported to be the most effective operative technique for grade III and IV hemorrhoids among various studies **Material & Methods:** Patients who were diagnosed clinically as third- and fourth-degree hemorrhoids and planned for conventional hemorrhoidectomy were enrolled by simple random sampling and randomized for two equal groups. Clearance from hospital ethics committee was taken before start of study. Written informed consent was taken from each study participant. **Results:** Out of the total study participants of group 1 10 (40%) were females and 15 (60%) were males. The mean age of study population was 36.2 ± 5.8 years. On the basis of degree of hemorrhoids 14 (56%) patients had third degree piles and 11 (44%) patients had fourth degree piles. The need for general anaesthesia was reported among 2/25 (8%) patients. The mean operative duration (minutes) was 22.54 ± 6.98. Out of the total study participants of group 2, 9 (36%) were females and 16 (64%) were males. The mean age of study population was 38.4 + 6.2 years. On the basis of degree of hemorrhoids 13 (52%) patients had third degree piles and 12 (48%) patients had fourth degree piles. The need for general anaesthesia was reported among 1/25 (4%) patients. The mean operative duration (minutes) was 21.32 ± 5.21. **Conclusion:** Local anesthesia for hemorrhoidectomy along with intravenous sedation is a safe procedure and should be considered as an alternative to spinal anesthesia. Present study reported that it has lesser postoperative pain scores, no hypotension, no headache and no urine retention in comparison to spinal anaesthesia.

Key words: Hemorrhoidectomy, Local anesthesia, Spinal anesthesia.

INTRODUCTION

Piles or hemorrhoids are a common disease diagnosed among adults. Previous studies reported that more than half population of males and females who aged 50 years and above were diagnosed with piles or hemorrhoid signs and symptoms **(1)**. Piles or hemorrhoids are characterized as the distal displacement and/or the symptomatic enlargement of the normal anatomy of anal cushions **(2)**. Various researchers had clinically classified piles or hemorrhoids into four grades. For the treatment of piles or hemorrhoid the most commonly used and widely considered operative technique is open hemorrhoidectomy and reported to be the most effective operative technique for grade III and IV hemorrhoids among various studies. The open hemorrhoidectomy operative technique was firstly used and operated by Milligan and Morgan, surgeons in the United Kingdom in 1937 **(3)**.

Excisional operative techniques for hemorrhoidectomy including the open hemorrhoidectomy technique and its other modifications are reported in various studies as a painful operative procedure. In previous studies, various attempts were made to reduce the postoperative pain such as suturing the vascular pedicle without incisions, limited incisions and stapled hemorrhoidectomy. Along with these modification in operative procedures various medications were also studied for postoperative pain such as local anesthesia, suppositories and oral medications **(4)**.

Among several studies local anesthesia was studied to decrease the postoperative pain after hemorrhoidectomy under general anesthesia or in some studies it was the only anesthesia applied for hemorrhoidectomy **(5)**. The benefits reported of local anesthesia includes reduction in postoperative pain, early recovery and reduction in hospital stay. However, the major complaint reported of local anesthesia for performing hemorrhoidectomy is severe pain during the injection of the local anesthesia because of the sensitive anoderm **(6)**. Various studies also conducted for evaluation of the effects and benefits of the general and spinal anesthesia along with their complications and need of preoperative preparation and duration of hospitalization till complete recovery. We conduct the present study to assess the benefits and complications of local anesthesia and spinal anesthesia for hemorrhoidectomy.

MATERIALS & METHODS

The present prospective study was conducted at our tertiary care hospital and the study duration was one year from January 2018 to December 2018. A sample size of 50 was calculated at 95% confidence interval at 5% of maximum allowable error. Patients who were diagnosed clinically as third- and fourth-degree hemorrhoids and planned for conventional hemorrhoidectomy were enrolled by simple random sampling and randomized for two equal groups. Clearance from hospital ethics committee was taken before start of study. Written informed consent was taken from each study participant.

All the data were recorded related to detailed clinical history, cause of admission, APACHE -2 scores, and co-morbidities. Patients with cardiovascular, renal disease, neurologic disease, hepatic diseases, diabetic mellitus, patients with associated anorectal problems, history of anorectal operations, patients who were taking anti-hypertensive, analgesics, antipsychotics or sedative medicines and pregnant or breast-feeding females were excluded from the present study. Study participants were divided in two groups 1st Group had surgery under local anesthesia with IV sedation and 2nd group underwent surgery under spinal anesthesia. All the study participants were subjected to electrocardiography, end tidal CO2, temperature and baseline cardio-respiratory parameters were also recorded. Data analysis was carried out using SPSS v22. All tests were done at alpha (level significance) of 5%; means a significant association present if p value was less than 0.05.

RESULTS

In the present study, we enrolled 50 patients who were who were diagnosed clinically as third- and fourth-degree hemorrhoids and planned for conventional hemorrhoidectomy and randomized for two equal groups. Out of the total study participants **(19)** 38% were females and (31) 62% were males. The mean age of study population was 37.55 ± 5.9 years. Study participants were divided in two groups 1st Group had surgery under local anesthesia with IV sedation and 2nd group underwent surgery under spinal anesthesia. Out of the total study participants of group 1 10 (40%) were females and 15 (60%) were males. The mean age of study population was 36.2 ± 5.8 years. On the basis of degree of hemorrhoids 14 (56%) patients had third degree piles and 11 (44%) patients had fourth degree piles. The need for general anaesthesia was reported among 2/25 (8%) patients. The mean operative duration (minutes) was 22.54 ± 6.98. Out of the total study participants of group 2, 9 (36%) were females and 16 (64%) were males. The mean age of study population was 38.4 ± 6.2 years. On the basis of degree of hemorrhoids 13 (52%) patients had third degree piles and 12 (48%) patients had fourth degree piles. The need for general anaesthesia was reported among 1/25 (4%) patients. The mean operative duration (minutes) was 21.32 ± 5.21. (Table 1)

Table 1: Distribution of study participants according to study parameters.

Study parameters		Group 1 (n=25)	Group 2 (n=25)
Mean age (years)		36.2 ± 5.8	38.4 ± 6.2
Gender	Male	15 (60%)	16 (64%)
	Female	10 (40%)	9 (36%)
Piles degree	Third	14 (56%)	13 (52%)
	Fourth	11 (44%)	12 (48%)
Need for general anaesthesia		2/25 (8%)	1/25 (4%)
Mean operative duration (minutes)		22.54 ± 6.98	21.32 ± 5.21

In the present study, out of the total study participants on the basis of Post-operative pain scores (determined by NRS), it was found that Post-operative pain scores were collectively less in local anaesthesia group. Out of the total study participants of group 1 the mean values of post-operative pain score, determined by NRS after 1st hour was 0.67, after 2nd hour was 0.91, after 4th hour was 2.0, after 6th hour was 2.2 and after 12th hour was 2.0. Out of the total study participants of group 2 the mean values of post-operative pain score, determined by

NRS after 1st hour was 0.42, after 2nd hour was 1.18, after 4th hour was 2.6, after 6th hour was 2.9 and after 12th hour was 2.8. These differences were statistically non-significant (p value > 0.05). (Table 2)

Table 2: Distribution of Post-operative pain Score among study groups.

Post-operative pain Score	Group 1	Group 2	p value
1st hour	0.67	0.42	>0.05
2nd hour	0.91	1.18	>0.05
4th hour	2.0	2.6	>0.05
6th hour	2.2	2.9	>0.05
12th hour	2.0	2.8	>0.05

In the present study, out of the total study participants on the basis of adverse effects, we found that bleeding was the most common adverse effect reported among the study groups of group 1st which was reported among 6(24%) patients. Delayed healing was present among 1 (4%) patients. None of the patient was reported for hypotension, headache, urine retention and deep infection. Out of the total study participants on the basis of adverse effects, we found that hypotension was the most common adverse effect reported among the study groups of group 2nd which was reported among 8 (32%) patients. Headache was present among 7 (28%) patients, bleeding was present among 5 (20%) patients, urine retention was present among 3 (12%) patients and delayed healing was present among 2 (8%) patients. None of the patient was reported for deep infection. (Table 3)

Table 3: Distribution of study participants according to adverse effects.

Adverse effects	Group 1	Group 2	p value
Hypotension	0	8 (32%)	< 0.05
Headache	0	7 (28%)	< 0.05
Bleeding	6(24%)	5(20%)	> 0.05
Urine retention	0	3(12%)	< 0.05
Delayed healing	1(4%)	2(8%)	> 0.05
Deep infection	0	0	> 0.05

DISCUSSION

In the present study, we enrolled 50 patients who were who were diagnosed clinically as third- and fourth-degree hemorrhoids and planned for conventional hemorrhoidectomy and randomized for two equal groups. Out of the total study participants (19) 38% were females and (31) 62% were males. The mean age of study population was 37.55 ± 5.9 years. Study participants were divided in two groups 1st Group had surgery under local anesthesia with IV sedation and 2nd group underwent surgery under spinal anesthesia. Similar results were obtained in a study conducted by Bansal H,et al for the Comparative study of assessment of the benefits and complications of local anesthesia and spinal anesthesia for hemorrhoidectomy. They reported similar results as the present study (7). Similar results were obtained in a study conducted by et al for the Comparative study of assessment of the benefits and complications of local anesthesia and spinal anesthesia for hemorrhoidectomy. They reported similar results as the present study (8).

In the present study, out of the total study participants of group 1 10 (40%) were females and 15 (60%) were males. The mean age of study population was 36.2 ± 5.8 years. On the basis of degree of hemorrhoids 14 (56%) patients had third degree piles and 11 (44%) patients had fourth degree piles. The need for general anaesthesia was reported among 2/25 (8%) patients. The mean operative duration (minutes) was 22.54 ± 6.98. Out of the total study participants of group 2, 9 (36%) were females and 16 (64%) were males. The mean age of study population was 38.4 ± 6.2 years. On the basis of degree of hemorrhoids 13 (52%) patients had third degree piles and 12 (48%) patients had fourth degree piles. The need for general anaesthesia was reported among 1/25 (4%) patients. The mean operative duration (minutes) was 21.32 ± 5.21. Similar results were obtained in a study conducted by D. G. Jayne,et al for the Comparative study of assessment of the benefits and complications of local anesthesia and spinal anesthesia for hemorrhoidectomy. They reported similar results as the present study (9).

In the present study, out of the total study participants on the basis of Post-operative pain scores (determined by NRS), it was found that Post-operative pain scores were collectively less in local anaesthesia group. Out of the total study participants of group 1 the mean values of post-operative pain score, determined by NRS after 1st hour was 0.67, after 2nd hour was 0.91, after 4th hour was 2.0, after 6th hour was 2.2 and after 12th hour was 2.0. Out of the total study participants of group 2 the mean values of post-operative pain score, determined by NRS after 1st hour was 0.42, after 2nd hour was 1.18, after 4th hour was 2.6, after 6th hour was 2.9 and after 12th hour was 2.8. These differences were statistically non-significant (p value > 0.05). Similar results were obtained in a study conducted by Craig T. Hartrick,et al for the Comparative study of

assessment of the benefits and complications of local anesthesia and spinal anesthesia for hemorrhoidectomy. They reported similar results as the present study **(10)**.

In the present study, out of the total study participants on the basis of adverse effects, we found that bleeding was the most common adverse effect reported among the study groups of group 1st which was reported among 6(24%) patients. Delayed healing was present among 1 (4%) patients. None of the patient was reported for hypotension, headache, urine retention and deep infection. Out of the total study participants on the basis of adverse effects, we found that hypotension was the most common adverse effect reported among the study groups of group 2nd which was reported among 8 (32%) patients. Headache was present among 7 (28%) patients, bleeding was present among 5 (20%) patients, urine retention was present among 3 (12%) patients and delayed healing was present among 2 (8%) patients. None of the patient was reported for deep infection. Similar results were obtained in a study conducted by Younes Hassan et al for the Comparative study of assessment of the benefits and complications of local anesthesia and spinal anesthesia for hemorrhoidectomy. They reported similar results as the present study **(11)**.

CONCLUSION

We concluded from the present study that use of local anesthesia for hemorrhoidectomy along with intravenous sedation is a safe procedure and should be considered as an alternative to spinal anesthesia. Present study reported that it has lesser postoperative pain scores, no hypotension, no headache and no urine retention in comparison to spinal anaesthesia.

ABSTRACT

Background and Aims: This study assesses the extubation practices of anaesthesiologists and whether these practices differ from existing guidelines. **Methods:** The literature related to tracheal extubation was searched and a validated questionnaire was designed to assess practices of tracheal extubation. The questionnaire included techniques, manoeuvres, preparation, timing and plan of extubation. The survey link was shared with eligible participants. The responses were assessed using Statistical Package for Social Sciences (SPSS) software. **Results:** Of the 1264 respondents, 66.8% keep difficult airway cart ready only when difficult extubation is anticipated. Only 12.3% of respondents perform deep extubation with supraglottic airway device (SAD) exchange while 73.3% of respondents perform awake extubation with pharmacological control for preventing haemodynamic fluctuations. In the case of anticipated difficult extubation, 48.3% anaesthesiologists prefer the airway exchange catheter (AEC) exchange technique. Of all, 84.8% anaesthesiologists administer 100% oxygen before performing extubation and 81.7% continue to oxygenate during and 83.9% provide oxygen after extubation in all patients. In the case of suspected airway edema or collapse or surgical cause for airway compromise, 70% anaesthesiologists perform a leak test. The most preferred plan of extubation in patients with suspected airway collapse after surgery is direct extubation in fully awake position (54.6%). In patients with anticipated difficult extubation, 50.8% anaesthesiologists prefer to ventilate for 24 hours and reassess. **Conclusion:** We observed that the extubation practices vary widely among anaesthesiologists. Almost half of the anaesthesiologists were unaware of extubation guidelines.

Key words: Difficult airway, difficult extubation, difficult intubation, extubation, surgical airway

INTRODUCTION

Tracheal extubation after completion of surgery is an important aspect of perioperative care for uneventful patient recovery. Tracheal intubation has always been given much emphasis, but extubation remains an ignored aspect in literature and clinical practice. Adverse events related to extubation include airway obstruction, laryngospasm, bronchospasm, aspiration, airway edema and so on which may lead to emergency reintubation. These events increase the risk of morbidity and mortality. Proper planning and its execution before extubation are of utmost importance, especially in the difficult airway. Various guidelines have been formulated to provide a structured approach and proper technique for extubation.[1,2] The knowledge and practice of these guidelines are important to optimise extubation practices for different scenarios to improve patient outcomes and minimise postoperative complications.

We designed a survey to assess the extubation practices among anaesthesiologists with regards to techniques, manoeuvres, timing, and plan of extubation in various situations and whether there were any differences in their practices from the existing guidelines.

How to cite this article: Thakore S, Kundra P, Garg R. A descriptive survey of tracheal extubation practices among Indian anaesthesiologists. Indian J Anaesth 2021;65:210-5

METHODS

The literature related to tracheal extubation was searched in various databases including Pubmed/ Medline, Cochrane, Scopus and Google Scholar. The existing difficult airway guidelines by All India Difficult Airway Association (AIDAA) and Difficult Airway Society (DAS) were also referred.[1,2] The keywords 'difficult airway', 'extubation', 'difficult intubation', 'difficult extubation', 'extubation and surgical airway', 'extubation and haemodynamics' in various combinations were used for literature search. The bibliography of the retrieved manuscripts was searched manually for any missing manuscripts.

Based on this literature, a questionnaire was designed to cover various aspects related to tracheal extubation. The questionnaire was designed as per the format for the online (web-based) survey.[3,4] A total of 25 questions were designed in the English language and all of them were closed-ended questions (multiple-choice or checkbox) except one open-ended question at the end of the survey. The questionnaire collected data about the experience and working place of anaesthesiologists, their techniques, manoeuvres, preparation, timing, and plan of extubation in various scenarios. The questionnaire was reviewed by 5 independent experienced anaesthesiologists (with experience of >10 years) and comments related to ambiguity, clarity, and relevance were sought. The questionnaire was revised accordingly as per the comments. In case of a difference in opinion among these, the consensus was achieved among the three researchers for the final survey question. The final survey was also shared with non-anaesthesiologists and three other experienced anaesthesiologists for a final review. The comments were requested about any ambiguity in words, language and understanding. The final revision of the questionnaire was thus made for its distribution.

The google form-based questionnaire was made and its web-based link was shared via e-mail and WhatsApp among anaesthesiologists working in India. One anaesthesiologist could participate once in the survey. Only anaesthesiologists who have completed their post-graduation in anaesthesia were included. The response was voluntary, and the anonymity of the participants was maintained. Their responses were recorded and assessed using Statistical Package for the Social Sciences (SPSS) software. The data collected about practice patterns were analysed using descriptive analysis.

RESULTS

We analysed the responses from 1264 respondents. Majority of the respondents (45.6%) had experience of more than 10 years and 55.2% were from the academic institutes [Table 1].

According to the data collected, it was observed that 66.8% of respondents keep difficult airway cart ready only when difficult extubation is anticipated while 30.4% keep difficult airway cart ready for all patients. In case of low risk for extubation (normal airway and intubation), where pharmacological control of haemodynamic parameters is required, only 12.3% of respondents perform deep extubation with supraglottic airway device (SAD) exchange, 73.3% of respondents perform awake extubation with pharmacological control for preventing haemodynamic fluctuations, and 14.4% perform direct extubation in a patient with low risk of extubation failure. During extubation in a deep plane of anaesthesia, the most common technique used was direct extubation followed by mask ventilation [Table 2]. In the case of anticipated difficult extubation, the majority (48.3%) anaesthesiologists prefer the airway exchange catheter (AEC) exchange technique for extubation [Table 2]. Most of the anaesthesiologists (60.3%) keep AEC for <2 h and few keep it for 2-12 h in situ. Very few (4.6%) keep it for >12 h.

Regarding oxygen supplementation, 84.8% anaesthesiologists administer 100% oxygen in all patients before performing extubation, 81.7% continue to oxygenate during the extubation process, and 83.9% provide oxygen after extubation in all patients [Table 3]. A time-based (for a fixed period) technique is most commonly used for delivery of 100% oxygen before performing extubation [Table 3].

The routine use of recruitment maneuvers before extubation was low and 54.7% of anaesthesiologists apply positive pressure in all patients during the

Table 1: Demographic profile of the respondents (*n*=1264)

Parameter	Options	Response *n* (%)
Experience in Anaesthesiology (after completing post-graduation)	<3 years	265 (21.1%)
	3-5 years	214 (16.9%)
	6-10 years	208 (16.4%)
	>10 years	577 (45.6%)
Workplace	Academic Institute	698 (55.2%)
	Corporate Hospital	318 (25.2%)
	Freelance practice	207 (16.4%)
	Others	41 (3.2%)

Table 2: Use of various techniques for difficult extubation (*n*=1264)

Parameter	Options	Response *n* (%)
Which technique do you perform for airway management during extubation in deep anaesthesia?	Supraglottic airway device (SAD) exchange (Bailey manoeuvre)	340 (26.9%)
	Direct extubation followed by mask ventilation	742 (58.7%)
	Extubation over airway exchange catheter	128 (10.1%)
	Other	54 (4.3%)
In case of anticipated difficult extubation, which advanced technique do you prefer for awake extubation?	Airway Exchange Catheter (AEC)	611 (48.3%)
	Laryngeal mask airway exchange/Bailey manoeuvre	289 (22.9%)
	Fiberoptic bronchoscope/Video endoscope exchange	120 (9.5%)
	Direct Extubation	243 (19.2%)
	Other	1 (0.1%)

Table 3: Peri-extubation oxygen supplementation (*n*=1264)

Parameter	Options	Response *n* (%)
Do you administer 100% oxygen before performing awake extubation?	All patients	1072 (84.8%)
	Selected patients (e.g.in anticipated difficult extubation)	154 (12.2%)
	Administer the same % of oxygen as intraoperatively	38 (3%)
Do you continue to oxygenate with 100% oxygen at the extubation process?	Yes	1032 (81.7%)
	No	88 (7%)
	Selected patients (e.g.in anticipated difficult extubation)	144 (11.4%)
Do you routinely provide oxygen supplementation after extubation?	Yes	1060 (83.9%)
	No	86 (6.8%)
	Selected patients (e.g.in anticipated difficult Extubation)	118 (9.3%)
Which technique do you use for delivery of 100% oxygen before performing extubation?	Time-based -for a fixed period (e.g., 1,2,3 minutes)	792 (62.6%)
	End-tidal oxygen (EtO_2) monitoring based	423 (33.5%)
	Other	49 (3.9%)

extubation process [Table 4]. The survey revealed that 62% of anaesthesiologists suppress haemodynamic responses in selected patients with normal airway and 8.3% suppress in the difficult airway. In the case of suspected airway edema or collapse or surgical cause for airway compromise, 70% anaesthesiologists perform a leak test and 17% were not sure. The qualitative method is used by most of them (47%) for the leak test.

The most preferred plan of extubation in patients with suspected airway collapse after surgery is direct extubation in a fully awake position (54.6%). In patients with anticipated difficult extubation (difficult mask ventilation/difficult intubation, delayed recovery because of pre-existing diseases), 50.8% anaesthesiologists prefer to ventilate for 24 hours and reassess [Table 5]. In difficult extubation cases with surgical cause for airway compromise/suspected airway edema/collapse, 65.2% prefer to ventilate for 24 hours [Table 5]. In case of high suspicion of airway edema, manoeuvre or drugs used before extubation were steroids (48%), nebulised epinephrine (28%), and head-up position (23%). Among the participants, 37.6% follow DAS guidelines, 19.8% follow AIDAA guidelines whereas 42.6% follow department protocol-based algorithms for extubation. As far as awareness of the difficult airway algorithm is concerned, 44% of anaesthesiologists were unaware of the extubation guidelines/algorithms. Various suggestions were invited to improve airway algorithms. Some of them were the inclusion of obstetric and paediatric extubation in difficult airway algorithms.

DISCUSSION

This survey focused on various practice patterns related to extubation planning, extubation techniques, and awareness of the extubation algorithm among anaesthesiologists. There is a scarcity of such information from anaesthesiologists. The reported data related to knowledge and awareness of extubation practices have not focused on techniques and plans of extubation.[5,6]

According to the data collected from all anaesthesiologists, it was observed that 66.8% of respondents keep difficult airway cart ready only when difficult extubation is anticipated while 30.4% of people keep difficult airway cart ready always in all patients.

We observed that the availability of difficult airway cart was not universal even when difficult extubation

Table 4: Use of recruitment manoeuvre and positive pressure for extubation (*n*=1264)

Parameter	Options	Response *n* (%)
Do you perform a recruitment manoeuvre (if not contraindicated) before extubation?	All patients	321 (26.4%)
	Selected patients (e.g. in anticipated difficult extubation)	541 (42.9%)
	Do not perform	402 (31.6%)
Do you apply positive pressure during the extubation process (endotracheal tube removal)?	All patients	691 (54.7%)
	Selected patients (e.g. in anticipated difficult extubation)	278 (22%)
	Don't apply	295 (23.3%)

Table 5: Extubation strategies in difficult extubation (*n*=1264)

Parameter	Options	Response
What is your preferred plan of extubation in patients with suspected airway collapse (leak absent/equivocal) after surgery?	Extubate under deep inhalational anaesthesia directly	28 (2.2%)
	Extubate under deep inhalational anaesthesia over AEC/FOB	430 (34%)
	Direct extubation in fully awake and observe	690 (54.6%)
What is the plan for extubation in difficult extubation cases with difficult mask ventilation/Difficult intubation/Delayed recovery/difficulty because of pre-existing disease?	Tracheostomy	116 (9.2%)
	Upfront tracheostomy	88 (7%)
	Extubate over Airway Exchange Catheter (AEC)/Fiberoptic bronchoscope (FOB)	471 (37.3%)
	Ventilation for 24 h and reassess	643 (50.8%)
	Other	62 (4.9%)
What is the plan for extubation in difficult extubation cases with surgical cause for airway compromise/ suspected airway edema/suspected airway collapse?	Upfront tracheostomy	215 (17%)
	Extubate over AEC/FOB	192 (15.2%)
	Ventilation for 24 Hours and reassess	824 (65.2%)
	Other	33 (2.6%)

is anticipated. Although ready access to alternative airway devices reduces risk and complications in the unanticipated difficult airway, according to guidelines difficult airway cart should be readily available in case of anticipated difficult extubation.[1,2,5,6]

In patients who require obtundation of haemodynamic responses like ocular, intracranial surgeries, etc., most of the anaesthesiologists (73%) prefer to do awake extubation with pharmacological control while only 12% prefer deep extubation. Both are the techniques described in low-risk algorithms of airway guidelines.[1,2] But most anaesthesiologists do not prefer deep extubation which may either be because of lack of expertise or lack of regular practice. Although deep extubation has many advantages e.g., decreased cardiovascular sympathetic stimulation, lesser incidence of cough, and laryngospasm, there is an increased incidence of respiratory complications after extubation under deep anaesthesia.[7,8] The anticipated respiratory complications may be one of the reasons for low rates of deep extubation.

In case of anticipated difficult extubation, AEC is the most preferred advanced technique followed by laryngeal mask airway (LMA) exchange (Bailey's manoeuvre) followed by direct extubation. AEC use has been supported by various airway guidelines and the evidence of successful reintubation through AEC is also sufficient.[1,2,5,9,10] LMA exchange is the first and most useful advanced technique described in DAS as well as AIDAA guidelines.[1,2] The safety and efficacy of this technique are well described in the literature.[11,12] A fibreoptic bronchoscope (FOB) is the least preferred technique for extubation in anticipated difficult extubation in our survey. This finding is also supported by a recent survey in the Indian scenario and most likely due to lack of expertise and less availability.[13] FOB may be of limited use because of its inherent limitation when used as an exchange catheter due to its stabilisation, expense, and risk of its breakage. It is also limited in its ability to oxygenate and monitor capnography through it because of its small lumen.[14] That may be the reason for not preferring FOB for difficult extubation. The AEC can be retained up to 72 hours as described in the literature.[5,6,12] However, the timing of retaining AEC should be individualised. In our survey, 60.4% of anaesthesiologists prefer to keep it *in situ* for <2 hours and 19% prefer to keep it from 2-12 hrs.

As far as oxygenation is concerned, 84% anaesthesiologists administer 100% oxygen before performing extubation in all patients and 82% continue to oxygenate throughout the extubation process and after extubation too. Extubation guidelines recommend providing preoxygenation with an inspired fraction of oxygen (FiO_2) 1 to build oxygen stores to provide

safe apnea time.[1,2,5,6] Although studies show that 100% oxygen increases the chances of atelectasis, the clinical significance is controversial.[15,16] During extubation, improving oxygen reserve takes a priority. To assess the delivery of oxygen before performing extubation, a time-based technique is most commonly employed (63%) in this survey followed by end-tidal oxygen (EtO_2) monitoring (33%). Although EtO_2 >90% is a better endpoint for the adequacy of oxygenation than a fixed period, its lesser utilisation maybe because of lack of availability and unfamiliarity of the technique and high cost associated with the technology.[1,2,18] AIDAA and DAS recommend applying recruitment manoeuvre (if not contraindicated) and positive pressure before extubation. However, only 43% of anaesthesiologists perform recruitment manoeuvres in selected patients and 55% apply positive pressure in all patients. Although reports of recruitment manoeuvre and positive pressure in the prevention of atelectasis have contradicting results, still guidelines have emphasised its importance in pre-extubation period.[17-20]

Haemodynamic responses secondary to extubation need to be obtunded and pharmacological measures like opioids are usually used. However, it can lead to sedation and respiratory depression post-extubation. Therefore, it should be done cautiously. AIDAA recommends haemodynamic suppression to be mandatory in the normal airway in a selected group of patients undergoing eye surgeries, vascular surgeries, intracranial surgeries, or thoracic surgical procedures in whom awake extubation is to be performed.[1] Only, 61% of anaesthesiologists perform haemodynamic suppression in the normal airway in a selected group of patients and 19% in all patients. The extubation failure may be seen in the difficult airway due to surgical cause (structural damage or nerve injury) or there is suspicion of postoperative airway edema or collapse (e.g., long-standing thyroid tumors, swelling, or another neck mass excision, obese patients or airway-related surgeries). A leak test is recommended in this group of patients to assess airway calibre and collapsibility.[1,21,22] In the present survey, 70% anaesthesiologists always perform, and 18% anaesthesiologists probably perform leak tests in such cases of suspected airway compromise. We observed that 47.5% prefer to perform qualitative tests and 33% prefer quantitative tests. Although the quantitative test is more accurate in identifying cuff leak, it is still not practised much probably because of the lack of proper techniques or lack of knowledge.[23,24] In patients with negative or equivocal leak test (suspected airway collapse), 55% anaesthesiologists prefer extubation when fully awake followed by extubation in deep inhalational anaesthesia over AEC/FOB (34%) followed by tracheostomy (9%). Both the techniques (awake as well as deep inhalational over AEC/FOB) have been described in AIDAA guidelines[1] whereas DAS guidelines[2] do not specify the technique for this specific group of patients, rather they have grouped such patients in 'at-risk group' for which awake extubation or advanced techniques are advised if it is safe to remove the tube. American Society of Anesthesiologists (ASA) taskforce recommends consideration of merits and demerits of deep extubation versus awake extubation in the difficult airway.[9] Deep extubation has been advocated to decrease the occurrence of coughing and laryngospasm. However, it may be associated with the risk of airway obstruction due to the decreased tone of the pharyngeal muscle.[25] Difficulty airway has been reported as one of the contraindications for deep extubation and thus avoided and awake extubation remains the preferred technique.[26,27] In difficult extubation cases with difficult mask ventilation/difficult intubation/delayed recovery/difficulty because of preexisting disease, 51% anaesthesiologists prefer delaying extubation and ventilate for 24 hours and reassess; 37.3% prefer to extubate over AEC/FOB and 6.7% prefer upfront tracheostomy. Even in patients with surgical cause for airway compromise, suspected airway edema, and collapse, 65.1% anaesthesiologists prefer to ventilate for 24 hours and reassess followed by 17% preferring upfront tracheostomy and 15.2% preferring extubation over AEC/FOB. Keeping asleep and intubated in the postoperative period and transfer to a critical care unit appears to be the safest option in anticipated difficult extubation cases provided proper precautionary measures are taken during transfer.[5,6,9] This is the most preferred option in our survey too. In case of high suspicion of airway edema, management options include head-up position, steroids, and nebulised epinephrine.[28-30] The most common method employed in our survey is steroids (48%) followed by nebulised epinephrine (28%) and head-up position (23%). Most of the anaesthesiologists may be using all simultaneously but steroids seem to be the first choice for airway edema.

Most of the anaesthesiologists follow departmental protocol-based algorithms for extubation (43%) followed by DAS (38%) and AIDAA guidelines (19.7%). It was observed that 44% of anaesthesiologists are unaware of the presence of extubation guidelines.

This depicts the need of improving awareness about the extubation guidelines to promote uniform and safe extubation practices. Some contraries to the present guidelines were also depicted in this survey. Aintree catheter guided extubation needs to be added to AIDAA guidelines. In case of the decision to delay extubation, extubation time may be shorter also (6-8 h) rather than 24 hr.

To conclude, we observed that the availability of difficult airway carts at extubation is not universal, the use of the pharmacological technique is a commoner technique to obtund haemodynamic response at extubation. The use of AEC is seen in half of the anaesthesiologists in anticipated difficult extubation. The majority provide 100% oxygen supplementation in the perioperative period. Almost half of the anaesthesiologists were unaware of extubation guidelines.

Case report

Abstract Central airway obstruction presents as an emergency with dyspnea and stridor. Anesthetic management of rigid bronchoscopy-guided tracheal stenting is highly stimulating procedure requiring general anesthesia. But it may lead to life threatening airway obstruction and cardiovascular collapse after induction. Total intravenous anesthesia based on propofol-remifentanil is an optimal anesthetic technique, but remifentanil is not available in many countries. Although dexmedetomidine-ketamine has been used for procedural sedation, its use for rigid bronchoscopy in the setting of central airway obstruction has not been described in literature. We describe near ideal anesthetic technique for management of central airway obstruction using dexmedetomidine-ketamine combination.

Introduction

Anesthetic management of Rigid Bronchoscopy (RB) guided tracheal stenting in patients with Central Airway Obstruction (CAO) poses unique challenges because the patient present as an emergency with high grade dyspnea and stridor with impaired oxygenation which provides us minimal time for optimization. It is a highly stimulating procedure and requires General Anesthesia (GA). But it may lead to life-threatening airway obstruction and cardiovascular collapse after induction of anesthesia. Total Intravenous Anesthesia (TIVA) based on propofol and remifentanil combination (intermittent boluses or continuous infusion)[1-3] is an optimal anesthetic technique but remifentanil is not available in many countries like ours. Remifentanil and propofol both cause hypotension and bradycardia and the effect

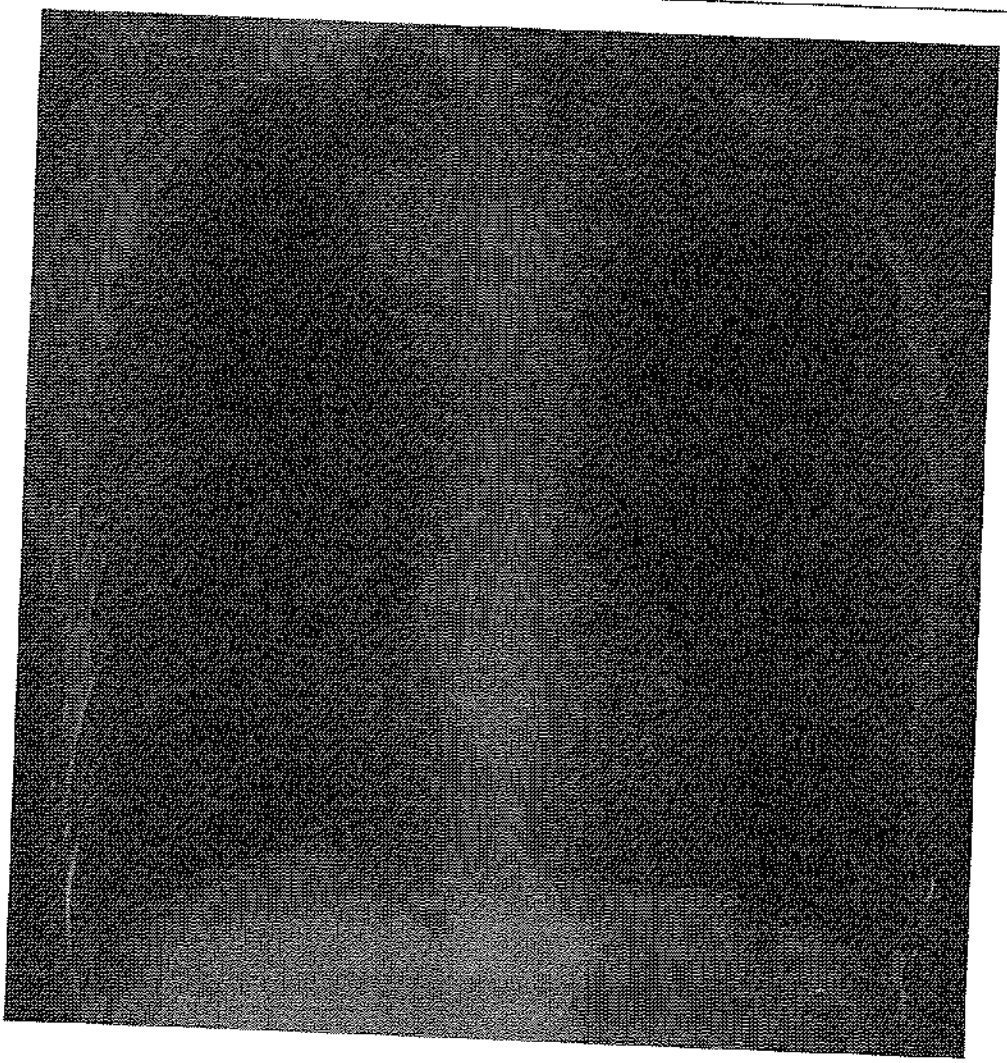

Figure 1

of their combination on hemodynamics can be synergistic. Ketamine, on the other hand, increases blood pressure and heart rate and is a good bronchodilator and analgesic but causes delirium, hallucinations, and increased salivation. Dexmedetomidine (DXM) reduces the side effects of ketamine and their combination provides hemodynamic stability. There are a few reports on the use of ketamine and DXM combination for procedural sedation.[4] DXM-ketamine infusion has not been reported to be utilized for GA in the setting of rigid bronchoscopy. We describe the use of combination of DXM-ketamine infusions for RB guided tracheal stenting in a patient with CAO.

Case report

A 55-year-old American Society of Anesthesiologists (ASA) physical status II patient weighing 56 kg presented to the emergency with cough, breathlessness (modified medical research council Grade 3)[5,6] and stridor. He was in respiratory distress with tachypnea (respiratory rate 22/minute) and usage of accessory muscles for respiration. On auscultation, patient had decreased air entry with bilateral inspiratory crackles with expiratory wheeze and audible stridor. Hemodynamic parameters were stable except tachycardia (pulse rate 120/min). Arterial Blood Gas (ABG) exhibited pH 7.31, PaO_2 63 mmHg, $PaCO_2$ 58 mmHg, and oxygen saturation (SpO_2) 89% on room air. Chest X-ray revealed mediastinal mass with tracheal compression and homogenous opacity in right middle lobe (Fig. 1). Computed Tomography (CT) scan demonstrated a large conglomerated lymph nodal mass in right paratracheal location (7 × 5 cm) infiltrating into tracheal lumen with significant narrowing of tracheal lumen with minimum diameter 3.5 mm (Grade 3 tracheal stenosis)[7] (Fig. 2). He was posted for RB-guided tracheal stenting under GA.

After confirming fasting status (6 hours) and obtaining written informed consent, the patient was taken to operation theatre. Preoperative counselling was done, and anesthesia risks related to loss of airway control, need of intubation and mechanical ventilation, need of intensive care unit, and perioperative pulmonary complications were explained to relatives. He was started on nebulization with salbutamol (2 mL, 2.5 mg) and budesonide (2 mL, 0.5 mg), and standard ASA monitors including Bispectral Index (BIS) monitor were attached. Preoxygenation was done with 10 L of 100% oxygen for 5 minutes in head-up position.

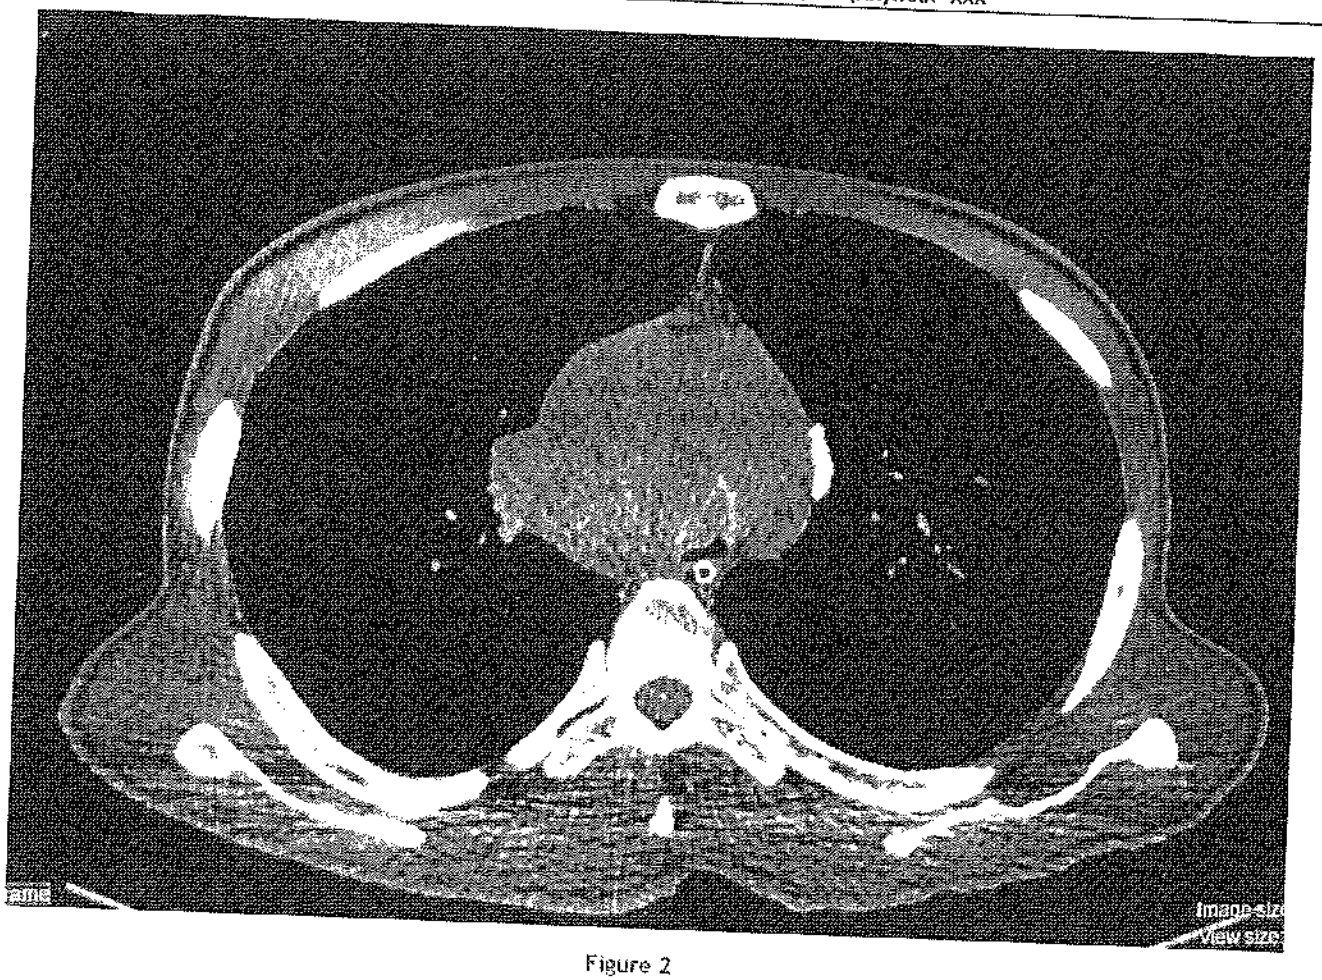

Figure 2

He received 0.2 mg glycopyrrolate, 8 mg dexamethasone and 75 μg fentanyl intravenously (IV). Thereafter, 0.5 $\mu g.kg^{-1}$ DXM was given over 10 minutes, and anesthesia was induced with 75 mg IV ketamine. Subsequently, 1 $mg.kg^{-1}$ intravenous (IV) succinylcholine was given and RB (Karl storz, size 11) was introduced in the trachea 60 seconds later. During maintenance phase, DXM (0.2–0.5 $mcg.kg^{-1}.h^{-1}$) and ketamine (0.5–1 $mg.kg^{-1}.h^{-1}$) infusions were titrated to achieve a BIS between 40–60. The patient was ventilated intermittently through anesthesia circuit attached to the ventilating port of the RB. Intraoperative ABG revealed improvement in oxygenation (PaO_2 75 mm) with slight increase in $PaCO_2$ (63 mm). The procedure lasted for 30 minutes and the patient was hemodynamically stable throughout the procedure. After the stent was placed, bronchoscope was removed, and I-gel size 4 was inserted. The infusion of DXM and ketamine was stopped, and the patient was extubated after ensuring good respiratory efforts with BIS of 80 after about 6 minutes of stopping the infusions. Postoperative ABG revealed Ph 7.37, PaO_2 80 mm, $PaCO_2$ 52 mm, and SpO_2 95%. He was conscious, oriented, pain free and was following commands. He was shifted to post anesthesia care unit for one day. Patient remained stable while maintaining SpO_2 95–96% on room air with normal neurocognition in the postoperative period. He was discharged the next day. His immediate postoperative period and follow up at one week was uneventful.

Discussion

Tracheal stenting in CAO is an emergency procedure and may not give enough time for preoperative optimization. It can lead to life threatening respiratory complications due to nature of disease, decreased oxygen reserve, or sudden airway collapse after anesthesia induction.

Propofol and remifentanil based TIVA is preferred technique over inhalational anesthesia.[2,6] Propofol is an IV hypnotic agent with short context sensitive half-life but it is painful on injection and does not provide analgesia. It may also cause suppression of airway reflexes, apnea, and hemodynamic instability due to vasodilatation and negative inotropy. Ketamine is an IV anesthetic agent with N-Methyl-D-Aspartate (NMDA) receptor blockade as the primary mechanism of action. Ketamine is a good analgesic with rapid onset of action (30 s) and causes bronchodilatation. But its usefulness is limited as it may cause delirium, hallucinations, emergence reactions, increased salivary secretions and hemodynamic instability (tachycardia and hypertension) due to sympathetic stimulation.[8]

DXM is a centrally acting alpha-2 adrenergic receptor agonist and produces sedation, anxiolysis and analgesia without respiratory depression. It enhances anesthesia produced by other anesthetic drugs, preserves airway reflexes and reduces delirium.[9–11] However, it may cause bradycardia and hypotension and has slow onset of action when used

as sole agent. A combination of DXM and ketamine may provide ideal anesthetic conditions like rapid onset, sedation, analgesia, amnesia, bronchodilation, hemodynamic stability, and maintenance of spontaneous respiration with minimal side effects. It may be an alternative to propofol and remifentanil in countries where remifentanil is not available. Moreover, it obviates the need of additional opioids and opioid related side effects.

DXM-ketamine combination has been used for procedural sedation with minimal cardiorespiratory adverse effects in patients undergoing esophago-gastro-duodenoscopy, in children undergoing minor cardiac procedures, and in pediatric dentistry.[11-13] Tobias has demonstrated descriptive accounts of reports from literature regarding the use of this combination for procedural sedation.[4] Apart from sedation, the effective and safe use of this combination has also been described for anesthesia in patients with uncorrected congenital cyanotic heart disease presenting for non-cardiac surgery.[14]

DXM-ketamine combination provided adequate sedation and comfort[15] with better hemodynamic stability than DXM alone[16] for awake fiberoptic intubation. RB procedure is associated with greater hemodynamic response for a longer time and optimum depth of anesthesia should be maintained throughout the procedure. Our patient presented in CAO with severe dyspnea and had low oxygen saturation that did not improve with any bronchodilators or steroids. As insertion of RB is highly stimulating, therefore depolarizing muscle relaxant was used for providing relaxation[17] due to its rapid onset, short duration, low cost, and better intubating conditions. So, emergency tracheal stenting was planned under general anesthesia with short acting neuromuscular block for induction followed by continuous infusion of DXM-ketamine combination that provided good anesthetic depth (objectively measured by BIS values) and hemodynamic stability without the need of additional doses of muscle relaxants. Further randomized studies are required to validate these findings in such category of patients.

Conclusion

DXM-ketamine based total intravenous anesthesia provides good analgesia, anesthesia, and hemodynamic stability with rapid, smooth induction, and emergence with minimal side effects. Hence it can be an ideal anesthetic technique for rigid bronchoscopic guided tracheal stenting.

Evaluating the Efficacy of Low-Dose Hyperbaric Levobupivacaine (0.5%) versus Hyperbaric Bupivacaine (0.5%) along with Fentanyl for Subarachnoid Block in Patients Undergoing Medical Termination of Pregnancy and Sterilization: A Prospective, Randomized Study

Sakshi Thakore, Nirdesh Thakore, Rama Chatterji, Chandra Shekhar Chatterjee, Samridhi Nanda

Department of Anesthesia, S.M.S. Medical College and Attached Group of Hospitals, Jaipur, Rajasthan, India

Abstract

Background: Spinal anesthesia using low doses of local anesthetics with opioids is emerging as a useful technique for day care surgeries. Levobupivacaine, a lesser toxic enantiomer of bupivacaine, has now been increasingly used in various gynecological surgeries. However, its use has not been demonstrated in medical termination of pregnancy (MTP) with sterilization (a kind of day care surgery). This study was performed to compare analgesic and anesthetic effectiveness of low-dose hyperbaric 0.5% levobupivacaine and hyperbaric 0.5% bupivacaine in combination with fentanyl in spinal anesthesia in patients undergoing MTP with sterilization. **Methods:** A comparative, randomized, double-blind study was conducted in 90 patients scheduled to undergo elective MTP with sterilization. Group levobupivacaine (L) (n = 45) received 7.5 mg (1.5 mL) of 0.5% isobaric levobupivacaine + 1 mL of 5% dextrose and fentanyl 25 mcg (0.5 mL), while group bupivacaine (B) (n = 45) received 7.5 mg (1.5 mL) of 0.5% hyperbaric bupivacaine + 1 mL of normal saline and fentanyl 25 mcg (0.5 mL). They were compared with respect to onset and duration of sensory and motor block, time to reach highest sensory level, time to two segments' regression, and total duration of analgesia. **Results:** Sensory and motor block onset and time to achieve highest level of sensory block were significantly delayed in group L ($P < 0.05$). Duration of sensory block and duration of analgesia was longer in group L than group B. Motor block duration was significantly shorter in L group (88.4 ± 12.4 min in group L and 133.9 ± 28.1 min in group B). Both groups were comparable in terms of hemodynamic parameters and adverse effects. **Conclusion:** This study suggests that 7.5 mg of 0.5% levobupivacaine usage in spinal anesthesia provides longer duration of analgesia and better sensory blockade with minimal motor block when compared with 0.5% bupivacaine along with fentanyl and may be a better alternative to bupivacaine in day care surgeries.

Keywords: *Bupivacaine, fentanyl, hyperbaric, levobupivacaine, medical termination of pregnancy, spinal anesthesia, sterilization*

Introduction

Spinal anesthesia is one of the anesthesia technique for medical termination of pregnancy (MTP) with sterilization.[1] It offers the advantage of patient being awake, oriented, breathing spontaneously, reduced postoperative pain, minimal postoperative nausea vomiting (PONV), and fast-track recovery and has emerged as a useful technique for day care surgeries.[2,3] For sterilization procedure, sensory level of at least T5-T6 is necessary to prevent discomfort from peritoneal traction, but increasing the dose of long-acting local anesthetics may produce extensive sensory and motor block as well as hypotension and this might result in delayed discharge from hospital.[4] Long-acting amide local anesthetics such as bupivacaine are used at low doses for outpatient spinal anesthesia.[5,6] Levobupivacaine is the S(-)-enantiomer of bupivacaine and is less toxic to heart and central nervous system.[7] It produces less motor block than bupivacaine when administered intrathecally at low doses.[8] Intrathecal fentanyl added to low-dose local anesthetics produces a synergistic effect without increasing the sympathetic block or delaying discharge.[9]

The aim of the study was to compare anesthetic and analgesic efficacy of

Quick Response Code:

low-dose hyperbaric levobupivacaine versus bupivacaine along with fentanyl in subarachnoid block in MTP with sterilization surgery. We hypothesize that levobupivacaine provides similar duration of analgesia without affecting duration of sensory and motor block when compared with bupivacaine.

Methods

This study was performed from February 2013 to January 2014. The study was registered with the Clinical Trials Registry of India (CTRI) with CTRI number 2016/12/007516.

After obtaining permission from the institutional ethical committee and written informed consent from the patients, this randomized, double-blind study was conducted in 90 patients. Inclusion criteria were american society of anesthesiologists (ASA) physical status I–II females between 20 and 50 years of age, weighing between 40 and 70 kg, and height >145 cm scheduled to undergo elective MTP with sterilization (tubal ligation) with gestation maximum up to 12 weeks. Patients with uncontrolled hypertension, infection at the injection site, disorders of coagulation, history of headache, reluctance to the procedure, neurologic disease, or hypersensitivity to amide local anesthetics or fentanyl were excluded from the study. All patients underwent a thorough preanesthetic checkup at least 24 h prior to surgery and were advised fasting 6 h before the procedure. Visual Analog Scale (VAS) was explained to patients.

In operation theater, electrocardiograph, noninvasive blood pressure (NIBP), and pulse oximeter were attached, and preoperative baseline readings of NIBP, pulse rate (PR), and oxygen saturation (SpO_2) were noted. A wide bore cannula was secured and preloading was done with Ringer lactate at 10 mL/kg. Patients were randomly allocated to two groups using computer-generated random number table and numbers concealed in opaque envelope to be opened after recruitment. This trial was so planned that neither the doctor nor the participant was aware of the group allocation and the drugs received.

Group A (n = 45) received 7.5 mg (1.5 mL) of 0.5% isobaric levobupivacaine (Levo-Anawin-Neon Laboratories Limited, Palghar Maharashtra, India) +1 mL of 5% dextrose and fentanyl 25 mcg (0.5 mL), while group B (n = 45) received 7.5 mg (1.5 mL) of 0.5% hyperbaric bupivacaine (Anawin Heavy-Neon Laboratories Limited, Palghar Maharashtra, India) +1 mL of normal saline and fentanyl 25 mcg (0.5 mL) making a total volume of 3 mL each. The intrathecal drugs were prepared by an independent anesthesiologist not involved in the conduct of case as per randomization and administered by another anesthesiologist blinded to group allocation. Under all aseptic precautions, spinal anesthesia was performed in the operating room at the L3–L4 or L2–L3 interspace, with the patient in the left lateral position. A total volume of 3 mL was injected slowly through a 25-G spinal needle. The patient was placed in supine position with a slight head down tilt immediately after spinal injection to achieve block level of T6.

Intraoperative vitals (blood pressure, PR, saturation and respiratory rate) were recorded at 2, 5, 10, 15, 30, 40, 50, 60 min, and postoperatively at 30 min interval or until rescue analgesic was given.

The primary outcome measure was comparison of analgesic efficacy of low-dose intrathecal levobupivacaine (7.5 mg) versus bupivacaine (7.5 mg) when combined with fentanyl 25 mcg. Secondary outcome measures were to compare sensory and motor block characteristics and hemodynamic effects of low-dose (7.5 mg) hyperbaric levobupivacaine (0.5%) and bupivacaine (0.5%) when they were combined with fentanyl (25 μg) in spinal anesthesia for MTP with sterilization surgery.

Total duration of analgesia was defined as time from intrathecal administration of drugs to patient's demand of rescue analgesic or VAS >3. It was recorded following pain scoring system – VAS. The VAS consisted of a 10-cm horizontal paper strip with two endpoints labeled 0 = "No pain" and 10= "Worst pain ever." VAS was serially assessed after completion of surgery at half an hour interval till 300 min or till the patient complained of pain (VAS >3). Patient's VAS >3 and administration of rescue analgesia constituted the end point of the study. Inj. diclofenac (75 mg) IV through infusion was given as rescue analgesic and 100 mg inj. tramadol IV through infusion if required.

The level of sensory block was tested by pinprick bilaterally at mid-clavicular line which was done every 2 min after spinal injection until it stabilized for three consecutive tests, and then every 15 min until S2 segment regression was achieved. "Onset of sensory block" was taken as the time taken to attain sensory level of T10 dermatome. Degree of motor block was assessed using modified Bromage scale (0: Able to move the hip, knee and ankle, 1: Unable to move the hip but is able to move the knee and ankle, 2: Unable to move the hip and knee but is able to move the ankle, 3: Unable to move the hip, knee, and ankle)[10] "Onset of motor block" was taken as the time taken to achieve Bromage scale 1 from the time of subarachnoid injection. "Onset of highest motor block" was recorded as time to reach highest scale of motor block (Bromage scale 2/3). "Motor block duration" was recorded as time to complete termination of motor block (Bromage scale 0). "Maximum motor block level" was recorded as highest motor block scale (Bromage scale) that was reached. Side effects recorded were hypotension (mean arterial pressure <60 mmHg or greater than 25% below the baseline), bradycardia (pulse <50/min), respiratory depression (oxygen saturation less than 90% or respiratory rate ≤8/min), and pruritus.

Episodes of intraoperative hypotension were managed with crystalloids 5 mL/kg, colloids, and if required with bolus doses of inj. mephenteramine 6 mg intravenously. Bradycardia was treated with 0.01 mg/kg of inj. atropine intravenously. Intraoperative nausea was treated with inj. ondansetron 4 mg and any pruritus was treated using antihistaminics. Oxygen (3 L/min) through face mask was applied if pulse oximeter reading decreased below 90%.

The surgical technique used was dilation and evacuation in lithotomy position followed by tubal ligation through minilaparotomy approach through suprapubic incision in supine position. On completion of the surgery, the patients were shifted to the recovery unit. These patients were discharged home once the complete resolution of motor and sensory blockade was achieved and they were able to stand on their feet with minimal or no assistance.

Statistical assessment of data was done using Statistical Package for the Social Sciences statistical software (version 17.0). The calculation of the required sample size was based on the mean and standard deviation (SD) of time to first rescue analgesia requirement after spinal anesthesia with bupivacaine (305 ± 50 min) and levobupivacaine (389 ± 189 min) as reported in previous trial,[10] and 36 patients were required for each group to reject null hypothesis of equality of means of two groups with alpha = 5% and power (1- β) = 90%. A total of 95 patients were assessed for eligibility and after exclusion and dropouts, 90 patients were analyzed (45 per group). Independent sample *t*-test was used to assess some of the demographic data (age, weight, and height), time to reach T10 dermatome, time to achieve highest sensory level, time to two segments' regression, time to onset of motor block, motor block regression time, and time to first dose of rescue analgesic. The changes in blood pressure and heart rate over time were tested with analysis of variance for repeated measures. Categorical variables such as ASA physical status and complications were analyzed by Chi-square test of significance. A value of <0.05 was considered significant and <0.001 was considered highly significant. Data were expressed as mean ± SD or median (range) or number of patients (*n*) or percentage (%).

Table 1: Demographic profile of the two groups

Duration of surgery (min.)	26.7±8.5	28.8±9.9	0.2909

Results

A total of 90 patients were analyzed in the study. Two patients in levobupivacaine group failed to achieve adequate surgical block within 30 min after spinal injection and performed under GA, and therefore withdrawn from the study. One patient in bupivacaine group had bladder perforation in which surgery was prolonged and GA had to be given, and therefore excluded from the study. The two groups were comparable with respect to age, gender, weight, height, ASA grade, and duration of surgical procedure [Table 1].

The duration of analgesia was significantly prolonged in levobupivacaine–fentanyl group than bupivacaine–fentanyl group ($P < 0.05$). Sensory and motor block onset and time to achieve highest level of sensory block were delayed in group L (levobupivacaine) when compared with group B (bupivacaine) with *P* value <0.05 (significant). Duration of sensory block was also longer in group L than group B. On the other hand, duration of motor block was significantly shorter in levobupivacaine group ($P < 0.001$) [Table 2]. There was no significant difference in terms of two segments' regression time and highest level of sensory block in both groups [Table 2]. T6 was the highest level of block achieved in a majority of patients in both groups, whereas few patients also achieved T8 level of block.

There was highly significant difference in maximum motor block achieved. In group B, The percentage of patients with complete motor block (Bromage scale 3) was significantly higher than group L ($P < 0.001$) [Table 3 and Figure 1].

Both groups were comparable with respect to mean arterial blood pressure, heart rate, and SpO_2 values over different time intervals [Figures 2 and 3]. There was no significant fall in MBP in both groups at any time interval. There

was no significant difference in the incidence of side effects (e.g. hypotension, bradycardia, nausea, vomiting, shivering, pruritus) in both groups ($P > 0.05$) [Table 4].

Discussion

We observed that 7.5 mg 0.5% hyperbaric levobupivacaine in spinal anesthesia can provide adequate sensory blockade with minimal motor block with longer duration of analgesia and stable hemodynamic profile when compared with similar dose and concentration of bupivacaine in MTP with sterilization surgery. Comparison of levobupivacaine and bupivacaine has been performed in various studies, but the results of them are inconsistent. Some studies have demonstrated equal effectiveness of levobupivacaine and bupivacaine, whereas others have shown different block characteristics. This is the first study performed in MTP

with sterilization surgery which is a type of ambulatory day care surgery.

Low-dose spinal anesthesia has been performed in this study which is the practice of using minimal dosing of intrathecal drugs to ensure that only the nerve roots supplying the specific area get blocked. According to a meta-analysis of 12 studies performed in 693 patients, a cut-off value was defined for "conventional dose" as >8 mg bupivacaine (which many would consider a low cut-off value) and "low dose" <8 mg.[12]

We have used hyperbaric solutions of levobupivacaine and bupivacaine in our study. Since literature describes use of various concentrations (mg/mL) of dextrose (3%[10]–50%[13]) to make solutions hyperbaric, we have used minimally concentration of dextrose (5%) using readily available solution to make levobupivacaine hyperbaric. We performed specific gravity testing on the mixtures before starting the study. The values of specific gravity of solutions were 1.015 in group L and 1.020 in group B, at 25°C respectively. As the specific gravity of cerebrospinal fluid (CSF) ranges from 1.0063 to 1.0075[14] and the mean CSF density of pregnant women was found to be 1.00033 ± 0.00010 g/mL,[15] both solutions were hyperbaric compared with CSF.

This study demonstrated longer duration of analgesia and longer duration of sensory block in levobupivacaine–fentanyl group. It may be related to vasoconstrictive properties of levobupivacaine at lower doses than bupivacaine.[3] Consistent with our study, Hakan Erbay *et al*.[11] and Erkili *et al*.[15] found that first analgesic requirement and duration of sensory block were longer in levobupivacaine than bupivacaine group. Long duration of sensory block in levobupivacaine group was also observed by Casati *et al*.[6] In contrast to this, Mehta *et al*.,[16] Lee *et al*.,[12] and Misirlioglu *et al*.[18] have demonstrated similar sensory block characteristics, whereas Duggal *et al*.[19] have revealed shorter duration of sensory block in levobupivacaine group which may be related to the fact that they have used isobaric levobupivacaine to compare with hyperbaric bupivacaine.

Studies performed by Misirlioglu *et al*.,[18] Erdil *et al*.,[20] and Vellosillo *et al*.[21] showed results similar to the present finding of delayed time to reach T10 level and highest level of sensory block in levobupivacaine group which again may have been the result of the vasoconstrictor properties of levobupivacaine.

The duration of the block is dependent on the type of the drug used and the volume. In our study, the effective concentration of the local anesthetic in both the groups was 0.25% and the volume was limited to 3 mL for both. Thus, the only difference was characteristic of the drug used. We found no significant difference in two segments' regression time and highest level of block achieved in both the groups ($P > 0.05$). In 2006, Vanna *et al*.[22] studied 70 patients undergoing elective transurethral endoscopic surgery who received 2.5 mL of either 0.5% isobaric levobupivacaine ($n = 35$) or 0.5% hyperbaric bupivacaine ($n = 35$) intrathecally and found that two groups were similar in terms of time to block suitable for surgery, duration of sensory block, time to two segments' regression, and time to T12 regression. In a recent study by Dar *et al*.,[23] 2 mL each of isobaric levobupivacaine 0.5% and hyperbaric bupivacaine 0.5% in combination with fentanyl 15 mcg were compared in spinal anesthesia in cesarean section and there was no significant difference in time to achieve highest level of block, two segment regression times, and incidence of side effects.

Our findings of delayed onset and short duration of motor block in levobupivacaine group are in congruence with Hakan Erbay *et al*.[11] and Duggal *et al*.[19] Erdil *et al*.[20] also illustrated delayed onset in group L, but similar degree and duration of motor block between two groups. Studies performed by Lee *et al*.[17] and Alley *et al*.[24] demonstrated no difference in motor block characteristics between levobupivacaine and bupivacaine.

We observed lesser percentage of patients with complete motor block in levobupivacaine group when compared with bupivacaine group. This was probably because levobupivacaine is less potent than bupivacaine. In the study of Camorcia *et al*.,[8] the potencies for motor block of intrathecal ropivacaine, levobupivacaine, and bupivacaine were compared, and weaker motor block potency and shorter duration of motor block were reported with levobupivacaine group. Dar *et al*.[23] also observed that regression time of motor block was significantly lesser in levobupivacaine group correlating with this study.

No clinically significant changes were observed in hemodynamic parameters (heart rate, mean blood pressure, peripheral oxygen saturation) throughout our study, and complications (hypotension, bradycardia, PONV, pruritus, shivering) were minimal and comparable in both groups. This may be related to usage of low doses of local anesthetics.[16]

There are certain limitations to our study. The sample size taken is small. Its implementation to a larger population group will need further research. In addition, since levobupivacaine was made hyperbaric by addition of 5% dextrose, whereas bupivacaine taken had 8% dextrose, the difference in the spinal characteristics may have been in part related to the difference in dextrose concentrations.

Conclusion

To conclude, 7.5 mg of hyperbaric levobupivacaine in addition to 25 mcg fentanyl provides adequate level of sensory blockade, with significantly lesser duration of motor blockade and longer duration of analgesia compared with similar dose of hyperbaric bupivacaine with the only disadvantage of delayed onset of sensory block. In addition,

low-dose levobupivacaine leads to a better hemodynamic profile compared with similar doses of bupivacaine. Thus, low-dose levobupivacaine plus fentanyl may be a better alternative to bupivacaine plus fentanyl owing to its longer duration of sensory block, good postoperative analgesia, and lesser degree and shorter duration of motor block allowing early ambulation and faster discharge.

ABSTRACT *Aims of Study : The aim of the study was to compare Intrathecal dexmedetomidine (Group D) and buprenorphine (Group B) in spinal anaesthesia for orthopaedic surgery in terms of onset and duration of sensory and motor block, haemodynamic parameters, post operative analgesia and side effects, if any.*

Methods : This comparative, randomized, double blind study was conducted in seventy patients scheduled to undergo elective orthopaedic lower limb surgeries. Group D (n=35) received 15 mg(3 ml) of 0.5 % hyperbaric bupivacaine + 5 mcg of dexmedetomidine + Normal saline to make the total volume 3.5 ml while Group B (n=35) received 15 mg(3 ml) of 0.5 % hyperbaric bupivacaine + 60 mcg of buprenorphine + Normal saline to make the total volume 3.5 mL Onset and duration of sensory and motor block, total duration of analgesia, hemodynamic parameters, post operative VAS score, number of rescue analgesics required and adverse effects were noted.

Results: There was no significant difference in sensory and motor block onset between 2 groups but significantly prolonged duration of sensory and motor block, and post operative duration of analgesia was seen in group D as compared to group B. Significantly reduced number of rescue analgesics were required in group D. Both groups were comparable in terms of hemodynamic parameters and no significant adverse effects were observed in both groups.

Conclusion : It was concluded that 5 µg dexmedetomidine as adjuvant to 0.5 % hyperbaric bupivacaine in spinal anesthesia provided prolonged duration of sensory and motor blockade and longer duration of analgesia and stable hemodynamic profile as compared to 60 µg buprenorphine.

INTRODUCTION

Spinal anesthesia is commonly employed technique for orthopaedic lower limb procedures and provides effective analgesia in early post operative period. Various adjuvants have been added to spinal local anaesthetic to prolong post operative analgesia.[1] Neuraxial adjuvants are utilised to increase the speed of onset of neural blockade (reduce latency), improve the quality and prolong the duration of neural blockade and for their dose sparing effects [2]. Buprenorphine is a mixed agonist – antagonist narcotic with high affinity at both mu (µ) and kappa opiate receptors. Lanz et al [3] demonstrated that buprenorphine is compatible with CSF and has no adverse effects when administered intrathecally. Intrathecal α2 receptor agonists have antinociceptive action for both somatic and visceral pain [4]. α2 receptor agonists administered intrathecally prolonged the analgesia provided by subtherapeutic doses of local anaesthetics like bupivacaine due to synergistic effects with minimal haemodynamic effects[5,6].

This study was aimed to compare the dexmedetomidine and buprenorphine as adjuvant in terms of onset and duration of sensory and motor block, haemodynamic parameters, post operative analgesia and side effects, if any.

METHODS:

After obtaining due permission from the institutional ethical committee and written informed consent from the patients, this hospital based, comparative, randomized , double blind study was conducted in seventy patients. Patients of ASA physical status I – II, age ranging between 30-50 years, height between 150-180 cm, who were scheduled to undergo lower limb elective surgeries. Patients with uncontrolled hypertension, infection at the injection site, disorders of coagulation, history of headache, reluctance to the procedure, neurologic disease or hypersensitivity to amide local anesthetics or dexmedetomidine and buprenorphine, were excluded from the study.

All patients underwent a thorough pre anesthetic checkup and were kept fasting overnight before the procedure. All routine monitoring were attached and preoperative baseline readings of Non Invasive Blood Pressure, Pulse Rate and Oxygen saturation were noted.

A good IV line was secured with 18G cannula and Ringer Lactate infusion was started. Patients were randomly allocated to two groups using chit in the box method. This trial was so planned that neither the doctor nor the participant was aware of the group allocation and the drugs received. Concept of VAS score was explained to patients.

Group D (n=35) received 15 mg(3 ml) of 0.5% hyperbaric bupivacaine + 5 mcg of dexmedetomidine + Normal saline to make the total volume 3.5 ml while Group B (n=35) received 15 mg(3 ml) of 0.5% hyperbaric bupivacaine + 60 mcg of buprenorphine + Normal saline to make the total volume 3.5 ml. The solutions were prepared by the anesthesiologist blinded to the study. Under all aseptic precautions, spinal anesthesia was performed in the operating room at the L3 – L4 or L2 – L3 interspace, with the patient in the sitting position. A volume of 3.5 ml was injected slowly through a 25-gauge spinal needle.

Intraoperative vitals (blood pressure, pulse rate, saturation) were recorded at 2,5,10,15,20,30,40,50,60 min interval and post operatively at 2, 4, 6, 8, 24 hr interval.

Onset of sensory block and motor block was noted using Modified Bromage score (0 : Able to move the hip, knee and ankle, 1 : Unable to move the hip but is able to move the knee and ankle, 2 : Unable to move the hip and knee but is able to move the ankle, 3 : Unable to move the hip, knee and ankle)

"Motor block duration" was recorded as time to complete termination of motor block.

"Maximum motor block level" was recorded as highest motor block

scale (Bromage score) that was reached.

Following side effects were recorded:

- Hypotension (MAP < 60 mmHg or greater than 20% below the baseline)
- Bradycardia (Pulse < 50/min)
- Respiratory depression (oxygen saturation less than 90%)
- Pruritus

Episodes of intra-operative hypotension were managed with intravenous fluids and if required, with bolus doses of inj. mephenteramine 6 mg intravenously. Bradycardia was treated with 0.01 mg/kg of inj. atropine intravenously. Intra-operative nausea and pruritus,if any, were planned to be treated using ondansetron and antihistaminics respectively.

Total duration of analgesia was defined as time from intrathecal administration of drug to patient's demand of rescue analgesic. It was recorded following pain scoring system - Visual analogue score. Patient's VAS>3 and administration of rescue analgesia constituted the end point of the study. Inj. diclofenac (75mg) IM was given as rescue analgesic.

STATISTICAL ANALYSIS:

The sample size was calculated 35 for each group at alpha error 0.05 and power 80 percent.

Statistical assessment of data was done by using SPSS Statistical software (ver. 17.0) Within group, paired t-Test and between groups, student t-Test were applied. For significance in difference in proportion of cases with complications, Chi - Square test of significance was applied. A value of <0.05 was considered significant and <0.001 was considered highly significant. Data were expressed as mean ± standard deviation (SD) or median (range) or number of patients (n) or percentage (%).

RESULTS:

A total of 70 patients were enrolled in the study and randomly assigned equally to one of two studied groups. The two groups were comparable with respect to age, gender, height, ASA grade. (Table 1,2)

Table 1

	Group-B		Group-D		P-Value between groups
	Group-B	SD	Group-D	SD

Characterstics of spinal anaesthesia: (Table 3)

Sensory and motor block onset were comparable in both groups with p value >0.05 (insignificant). Duration of sensory block and motor block was longer in group D than group B (p<0.001) and the difference was highly significant. Duration of analgesia was significantly longer in group D than group B (p<0.05).(Fig 1) Lesser number of rescue analgesics were required by the patients in dexmedetomidine group as compared to buprenorphine group. (Fig 2)

Fig 1. Duration of analgesia

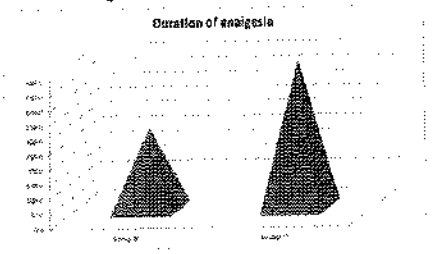

Fig 2. Number of rescue analgesics

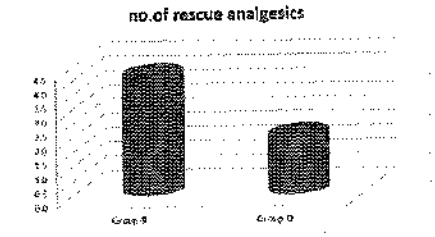

Table 3. Characteristics of spinal anaesthesia

	Group-B		Group-D		P-Value between groups

Intraoperative and postoperative hemodynamic changes:

Both groups were comparable with respect to heart rate and mean arterial blood pressure values over different time intervals. (Fig.3,4) No significant difference was found between the two groups regarding fall in Mean Blood Pressure at different time intervals.

Fig 3. Trends of pulse rate in both groups.

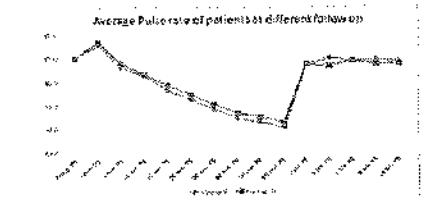

Fig 4. Trends of Mean Arterial Pressure in both groups.

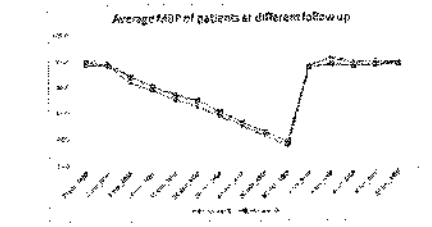

Complications

There was no significant difference in the incidence of side effects

(e.g. hypotension, bradycardia, nausea, vomiting, shivering, pruritus) in both groups (p>0.05) In group D 34.3 % patients and in group D 37.1 % patients showed hypotension (Table 4)

	35	100.0	35	100.0	

DISCUSSION

70 patients of similar demographic profile and ASA physical status1 and 2 were studied. Using 5 mcg dexmedetomidine provided longer duration of analgesia,sensory and motor blockade as compared to the use of 60 mcg of buprenorphine when added to 15 mg 0.5% hyperbaric bupivacaine.

Different agents have been used as adjuncts for prolonging the duration of spinal anaesthesia. Al - Ghanem et al.'s[13] study concluded that 5mcg dexmedetomidine seems to be effective as adjuvant to spinal bupivacaine in surgical procedures and provided adequate post operative analgesia. Therefore dexmedetomidine in a dose of 5 mcg was used in the present study.

Narcotics co administered with local anaesthetics intrathecally have a potent synergistic effect[14] . Buprenorphine is a centrally acting partial opioid agonist and has both spinal and supraspinal component of analgesia. Added to Bupivacaine intrathecally, it improved the quality and duration of postoperative analgesia compared to Bupivacaine alone.[15]. Shaikh et al. showed that 1 µg/kg Buprenorphine to a maximum of 50 µg when added to 15 mg of 0.5% heavy Bupivacaine intrathecally provides analgesia for 476.6±93.7 minutes.[16] .So in present study, buprenorphine in the dose of 60 mcg was used.

The duration of analgesia in buprenorphine group in present study was found to be 275.9 minutes which is lesser than the results observed by Capogna et al.,[17] where the duration of analgesia was 430 minute in the buprenorphine group. This could be because Capogna studied elderly patients. In present study,we found that the duration of analgesia in the dexmedetomidine group was 499.8 minutes. This is comparable with studies done by Shah et al.[18], where 5µg dexmedetomidine had a duration of analgesia 474 minutes. Duration of analgesia was significantly prolonged with the addition of 5µg dexmedetomidine to 478 minutes in the study done by Gupta et al[19]. In a similar study done by Nayagam et al[20], the duration of analgesia after addition of 5 mcg of dexmedetomidine was found to be 8.20 +/- 2.78 hrs which is found to be in resonance with our results.Study done by Eid et al.[11], showed that duration of analgesia with dexmedetomidine is proportional to its dose.

The onset of sensory and motor block in present study was comparable with the studies done by Shukla et al.,[12] and Shaikh and Kiran [16] for dexmedetomidine and buprenorphine respectively. The onset of sensory block in buprenorphine group according to a study done by Fauzia A. Khan et al [15] showed it to be 4.3 +/- 1 min where they used a buprenorphine dose of 30 mcg. The duration of sensory block in present study was 223.9 min in Buprenorphine group and 449.8 min dexmedetomidine group. Similar results have been shown in the study done by Mahima Gupta et al. [19]

The duration of motor block in present study was 398.8 minutes in the dexmedetomidine group which is comparable with the studies done by Gupta et al.,[19] where duration of motor block was 421 minutes.In a study done by Yektas et al [21], the duration of motor block with dexmedetomidine was found to be 226.5 min. This is probably because a lower dose of dexmedetomidne, 4mcg, was used in their study. The duration of motor block is significantly prolonged in comparison to duration of motor block in the buprenorphine group, 199.9 minutes which is in accordance with the study done by Mahima Gupta et al[22]

α2-adrenoceptor agonist bind to pre-synaptic C-fibres and post-synaptic dorsal horn neurons. Their analgesic action is due to depression of the release of C-fibre transmitters and by hyperpolarisation of post-synaptic dorsal horn neurons.[23] It may be an additive or synergistic effect secondary to the different mechanisms of action of the local anaesthetics and the α2-adrenoceptor agonist as studied by Salgado et al. [24] This antinociceptive effect may explain the prolongation of the sensory block when added to spinal anaesthetics. The prolongation of the motor block of spinal anaesthetics is due to the binding of α2-adrenoceptor agonists to motor neurons in the dorsal horn.[25,26]

A trend of decrease in pulse rate was observed in both the groups after the subarachnoid block was performed. But none of the patients in present study needed any intervention in the form of iv atropine throughout the surgery. This is in accordance with the study done by Dixit et al [27] where no case of bradycardia was seen in the buprenorphine group. In a study conducted by Mahmoud M. Al-Mustafa et al [28] only 1 case of bradycardia was reported when a 5 mcg dose of dexmedetomidine was used while no case of bradycardia was seen when a dexmedetomidine dose of 10 mcg was used and this supports the results of present study. Dexmedetomidine causes bradycardia but the effect is more prominent when administered intravenously and with a higher dose[29].

A trend of decrease was observed in the MAP readings in both the groups of present study. Hypotension was observed in 13 patients in buprenorphine group and 12 patients in dexmedetomidine group. The fall in MAP observed in the Dexmedetomidne group is similarly shown in the study conducted by Nayagam et al [11]. The fall in MAP observed in the Buprenorphine group is similarly shown in the study done by Fauzia A. Khan et al[15]. Sedation scores for dexmedetomidine were observed in a study done by Rajni Gupta et al [18] This action of dexmedetomidine is attributed to its action on the α-2 receptors in locus ceruleus. Sedative effects of Dexmedetomidine are prominent when given as intravenous bolus, continuous infusion, or Intramuscular injections[27].

Lesser number of rescue analgesic doses were required by the patients in dexmedetomidine group (2+/- 0.7) as compared to buprenorphine(4.1+/-0.9). Gupta et al[14] also concluded that after addition of dexmedetomidine 5 mcg to ropivacaine,less number of rescue analgesics were required in the first 24 hrs. The α-2 adrenergic agents also have antishivering property as observed by Talke et al.,[28] but no incidence of shivering was found in both the groups in present study. No incidences of nausea, vomiting, respiratory depression were observed in any of the patients in present study. Buprenorphine is partial agonist with high molecular weight and lipophilic, which may prevent its rostral spread and thus respiratory depression, prolongs the duration of sensory block and hence decreases the need for postoperative analgesia [29]. It was concluded that, the onset of sensory and motor blockade with both dexmedetomidine and buprenorphine were comparable. The duration of motor and sensory block in dexmedetomidine group was significantly longer as compared to buprenorphine group. Similarly duration of analgesia was also significantly longer in dexmedetomidine group as compared to buprenorphine group.

CONCLUSION:

Hence we concluded that intrathecal dexmedetomidine 5µg when compared to intrathecal buprenorphine 60µg caused prolonged duration of sensory and motor block and duration of analgesia. The requirement of rescue analgesia was lesser in dexmedetomidine group and the haemodynamics are similar in both the groups without causing any significant side effects.

SUMMARY

The use of laser for airway lesions requires airway management. Usual options include special laser-resistant endotracheal tubes. The use of supraglottic devices have been described in the literature. Laryngeal mask airway carries the risk of cuff damage during the use of laser. i-gel is made of thermoplastic material and does not require air inflation and thus potentially reduce the risk of cuff rupture. i-gel use in laser surgeries has not been described in the literature. We present successful airway management in laser surgery for bronchial tumour using i-gel.

BACKGROUND

Light amplification by simulated emission of radiation (laser) has been used for treatment of benign (colon and rectal polyps) and malignant conditions (head and neck cancers, lung cancer, liver tumours). The use of laser for airway lesions requires anaesthesia and a secured airway. Various options for securing the airway include laser-resistant endotracheal tubes, wrapped tubes and jet injector. Laryngeal mask airway (LMA) has also been described for airway management.[1] LMA allows uninterrupted ventilation along with the use of fibreoptic bronchoscope through it.[1 2] In spite of the benefits, LMA carries the potential risk of cuff damage during laser use leading to inadequate ventilation and thus risk of hypoxia. i-gel has the specific advantages of non-inflatable cuff and the possibility of tracheal intubation through it, if required. Until now, i-gel use in laser surgeries has not been described in the literature. We describe successful airway management in laser surgery for bronchial laser ablation of a lung tumour using i-gel. Written consent was taken for publication of this case from the patient.

CASE PRESENTATION

A 61-year-old man presented with chief complaints of cough, haemoptysis and fever since 1 year. Contrast enhanced CT scan revealed heterogeneously enhancing mass lesion in lingular lobe of left lung, upper lobe collapse and multiple enhancing mass lesions in both lobes of liver. Positron emission tomography CT findings revealed somatostatin expressing disease in left upper lobe bronchus and liver metastasis. Flexible video-bronchoscopy performed under local anaesthesia revealed left upper lobe occluded by a vascular tumour along with purulent secretions. Bronchial washings confirmed the diagnosis of neuroendocrine tumour of left upper lobe bronchus.

DIFFERENTIAL DIAGNOSIS

In view of respiratory distress caused by proximal bronchus obstruction by tumour mass, laser debulking of tumour was planned. Pulmonary function test demonstrated moderately restrictive defect.

TREATMENT

In the bronchoscopic suite, after securing the intravenous access, intravenous hydrocortisone 100 mg was administered. Standard monitors including 5-lead ECG, pulse oximeter (SpO_2) and non-invasive blood pressure were attached. The patient was preoxygenated with 100% oxygen for 5 min at a flow rate of 15 L/min in 40° head up position. Anaesthesia was induced in head up position (40°) using intravenous fentanyl 100 µg, propofol 100 mg and rocuronium 60 mg. A continuous intravenous infusion of propofol 200–300 µg/kg/min was started. Lungs were ventilated using positive pressure ventilation. Three minutes later, rigid bronchoscope was inserted. On evaluation, growth was visualised in left upper lobe bronchus. Intermittent manual jet ventilation was started through side port (ventilating port) of rigid bronchoscope. Because of excessive air leak from and around the rigid bronchoscope, ventilation was ineffective. The pulmonary interventions of laser ablation required period of apnoeas and low inspired fraction of oxygen (FiO_2). So the ventilatory strategy was required to be changed. We modified our plan to perform ventilation through i-gel (supraglottic airway device) and perform laser ablation of tumour by inserting laser probe through flexible fibreoptic bronchoscope which is in turn inserted through the i-gel using an swivel connector (figure 1). I-gel (figure 2) of size 4 was inserted and positive pressure ventilation was initiated. The procedure was started with continued ventilation. During laser ablation, to minimise the risk of airway fires, FiO_2 was reduced to 0.30 and fresh gas flow was increased to 10 L to expedite clearance of oxygen in the airway. All routine laser safety precautions were followed including draping the patient with moist towels and eye pads, and antiglare glasses were worn by all the personnel. Flexible fibreoptic bronchoscopy was performed through swivel catheter mount and endobronchial neodymium-doped yttrium aluminium garnet (Nd:YAG) laser (23 W/cm^2, continuous mode) applied. During laser ablation, intermittent apnoea was provided. High-force suction was applied through bronchoscope to remove laser fumes. During desaturation episodes below 90% of oxygen saturation as assessed by SpO_2, use of laser was stopped and intermittent positive

23 Anesthesia for Interventional Pulmonology

— *Dr. Sakshi Thakore, Dr. Sachidanand Jee Bharati, Dr. Karan Madan, Dr. Vinod Kumar*

INTRODUCTION

Interventional pulmonology is a rapidly evolving field of pulmonary medicine. The role of pulmonologists involves not only early diagnosis, risk stratification and management of lung disorders using minimally invasive techniques but also palliative procedures for inoperable and long standing diseases and their complications. The need of advanced bronchoscopic and pleuroscopic techniques for the diagnosis and treatment of a wide spectrum of thoracic disorders has increased in recent past.[1-4] Many of these procedures can be performed without anesthesia but others require varying levels of anesthesia ranging from local anesthesia to conscious sedation under monitored anesthesia care (MAC) for short and simple procedures to general anesthesia for complex and long duration procedures.

INTERVENTIONAL PULMONOLOGY SUITES

Disease processes requiring interventional pulmonology include complex airway pathologies, benign and malignant central airway obstruction, pleural diseases, and pulmonary vascular procedures.[5] Central airway obstruction (CAO) is a common clinical condition that leads to significant morbidity and mortality. CAO refers to obstruction in trachea and mainstem bronchi resulting from malignant or non malignant causes. The most common cause of malignant CAO is direct extension from an adjacent tumor most commonly bronchogenic carcinoma, followed by esophageal and thyroid carcinoma. The nonmalignant causes include infection, trauma, granulation tissue, vascular lesions and other entities like Sarcoidosis, Wegner's Granulomatosis, lymphadenopathy, tracheomalacia, post intubation tracheal strictures and bronchomalacia.[6]

Diagnostic and therapeutic procedures pertaining to these suites include, but are not limited to, rigid bronchoscopy, transbronchial needle aspiration (TBNA), endobronchial ultrasound (EBUS), transthoracic needle aspiration and biopsy, laser bronchoscopy, endobronchial electro surgery, argon-plasma coagulation, cryotherapy, airway stent insertion, balloon bronchoplasty and dilatation techniques, endobronchial radiation (brachytherapy), photodynamic therapy, percutaneous dilatational tracheotomy, transtracheal oxygen catheter insertion, medical thoracoscopy, and image-guided thoracic interventions (Table 1)

Anesthesia for Interventional Pulmonology

Introduction:

Interventional pulmonology is a rapidly evolving field within pulmonary medicine. The role of pulmonologists involves not only early diagnosis, risk stratification and management of lung disorders using minimally invasive techniques but also palliation of inoperable and long standing diseases. The need of advanced bronchoscopic and pleuroscopic techniques for the diagnosis and treatment of a wide spectrum of thoracic disorders has increased in recent past.[1–4] Many of these procedures can be performed without anesthesia but others require varying levels of anesthesia ranging from local anesthesia to conscious sedation under monitored anesthesia care (MAC) for short and simple procedures to General anesthesia for complex and long duration procedures.

Interventional Pulmonology Suites:

Disease processes requiring interventional pulmonology include complex airway pathology, benign and malignant central airway obstruction, pleural diseases, and pulmonary vascular procedures.[5] Central airway obstruction (CAO) is a common clinical condition that leads to significant morbidity and mortality. CAO refers to obstruction in trachea and mainstem bronchi resulting from malignant or non malignant causes. The most common cause of malignant CAO is direct extension from an adjacent tumor—most commonly bronchogenic carcinoma, followed by esophageal and thyroid carcinoma. The non malignant causes include infection, trauma, granulation tissue, vascular lesions and other entities like sarcoidosis, wegner's granulomatosis, lymphadenopathy, trachemalacia, bronchomalacia. [6]

Diagnostic and therapeutic procedures pertaining to these suites include, but are not limited to, rigid bronchoscopy, transbronchial needle aspiration (TBNA), endobronchial ultrasound (EBUS), transthoracic needle aspiration and biopsy, laser bronchoscopy, endobronchial electrosurgery, argon-plasma coagulation, cryotherapy, airway stent insertion, balloon bronchoplasty and dilatation techniques, endobronchial radiation (brachytherapy), photodynamic therapy, percutaneous dilatational tracheotomy, transtracheal oxygen catheter insertion, medical thoracoscopy, and image-guided thoracic interventions (Table 1)

Need of Anesthesia:

The field of interventional pulmonology involves diagnostic as well as therapeutic approaches. Whether there is need of anesthesia or not, it is usually decided by the pulmonologist and depends on the operators experience and level of comfort with a particular technique. It depends upon many factors which include type of procedure, its complexity and duration, patient's general condition and associated co-morbidities, patient's level of cooperation and consent. Anesthesia had not been discovered at the time when the rigid bronchoscope was discovered in 1865 by Dr. Killian (7), and the procedure was performed in conscious patients. In 1884, cocaine was introduced (first local anesthetic) which improved patient's comfort as well as physician's

methodology. But the effectiveness of local anesthetic is limited by its absence of anti anxiety properties and incomplete patient satisfaction [8,9]. Moreover, local anesthetics can't be used repeatedly for prolonged procedures because of possible toxicity with high doses. Conscious sedation with anti anxiety and/or analgesic drugs, alone or in combination with local anesthesia, has become the preferred method of anesthesia for routine outpatient diagnostic bronchoscopy procedures[10]. However, there is wide variation in drug doses required to achieve the desired effect. Complications related to conscious sedation are also variable and include prolonged period of amnesia, hypoventilation, hypoxemia, loss of airway patency, and hemodynamic instability [11]. As the field of interventional pulmonology is expanding, general anesthesia is emerging as a safe technique in patients undergoing long duration and technically complex procedures especially in patients with severe comorbidities and compromised central airway.

Anesthetic Challenges:

Although procedures requiring GA are performed in OR, many of the procedures performed through flexible bronchoscope in diagnostic bronchoscopy are carried out outside operating rooms. Many of the patients planned for an IP procedure are high risk patients either because of underlying lung condition or presence of co-morbidities. Secondly, anesthesia for interventional pulmonology requires sharing of airway with pulmonologist, the dynamic nature of the procedure given the continuously changing airway, fraction of inspired oxygen (FiO2) and finally, the ventilation mode to accommodate the procedure being performed. All these represent a unique challenge to the anesthesiologist. The anesthesiologist needs to be familiar with the different IP procedures (Table 1) and needs to develop an anesthetic and airway management plan specific for these airway interventions especially in high-risk patients.

Table 1: Interventional Procedures Organized by Disorders of the Chest [12]

Central Airway Obstruction	Diagnosis of Pulmonary Lesions	Artificial Airway	Pleural Disease

Coagulation (APC) o Electrocautery o Cryotherapy o Brachytherapy o Photodynamic therapy (PDT)	Endobronchial Ultrasonography **Early Detection of Lung Cancer** o Autofluorescence bronchoscopy o Narrow band imaging o Confocal bronchoscopy		

Preoperative Evaluation:

Preoperative evaluation has several important considerations. Important facts to consider are whether the procedure is elective or emergent and how stable the airway is. In elective cases, preoperative assessment is usually conducted with special attention to the following:

• Evaluation of airway, symptoms of compromise: dysphagia, hoarseness, orthopnea, stridor, the use of accessory muscles of respiration

• Review of the pulmonologist's notes on the size, extent and location of the lesion or tumor and the intended procedure(s).

• Review of computerized tomographic scan of the neck and chest to find out extent of airway obstruction and presence of any mediastinal masses.

•Review of pulmonary function tests (if available), extent of obstruction/restriction. In patients with significant airway compromise or respiratory distress, PFT's are usually not performed.

- Flow volume loop is simple and readily available tool to assess any form of airway obstruction. Special attention should be focused on inspiratory curve to suspect upper or central airway obstruction. However, clinician should comment on serial and repeatable inspiratory curve abnormalities as isolated abnormal inspiratory curve may suggest poor inspiratory effort rather than CAO.[13] Another limitation of flow volume loops is that characteristic blunting of flow volume loops can not be appreciated until tracheal lumen has narrowed to <8mm (≥ 80% tracheal narrowing).[14]

- Most studies have demonstrated low sensitivity of morphological criteria, but quantitative criteria has shown to have high sensitivity and high specificity in detecting CAO. Two ratios: a) Mid-vital capacity ratio (FEF50%/FIF50%) ≥ 1 and b) Empey's index which is the ratio of forced expiratory volume in 1s (FEV_1) and peak expiratory flow (PEF); (FEV1/PEF) ≥ 8 $mL \cdot L^{-1} \cdot min^{-1}$ are associated with the location, type and degree of central airway obstruction. Therefore, quantitative evaluation is extremely important to assess CAO.[15,16]

• Prior chemotherapy and any effects on vital organs (especially the heart and lungs)

• Commonly associated conditions, such as heavy smoking, tobacco chewing and alcohol use

• Common comorbidities: coronary artery disease, chronic obstructive/restrictive pulmonary disease, chronic alcoholism, malnutrition and aspiration pneumonitis.

Premedication:

In presence of significant airway obstruction, premedication with sedatives and anxiolytics should be minimized as many of these are known to have respiratory depressant effects. International guidelines suggest benzodiazepines to be the preferred agent for sedation during flexible bronchoscopy because of their favorable benefits of sedation, anterograde amnesia, decreased patient anxiety, improved tolerance of procedure, willingness of patients to undergo a repeat procedure, and improved working conditions for physicians.[17] Among benzodiazepines, midazolam is the most commonly used owing to its quick onset of action, rapid peak effect, and relatively short duration. Dose recommended for midazolam is 0.06 to 0.07 mg/kg according to International guidelines.[17] However, midazolam premedication must be carefully considered in hypoxemic critically ill patients because of persistent drowsiness and episodes of desaturation [18]

Atropine and glycopyrrolate have been used as premedication in bronchoscopic procedures because of their potential effects including drying of secretions to allow better examination of the tracheobronchial tree, protection against vasovagal reaction and bronchospasm. They also improve pulmonary function when given prior to bronchoscopy by either IV or IM route, however, this sustained effect is not seen through the post bronchoscopy period. [19,20] International guidelines have discouraged their use because of no clinically significant improvement in lung function or drying of bronchial secretions with atropine or glycopyrrolate. [17] In view of the available evidence, their use cannot be recommended at present.

Many clinicians use corticosteroids, particularly dexamethasone, as a premedication to decrease airway edema after airway surgery prophylactically. Common scenario when steroids may help reduce postoperative vocal cord edema include: cases where there are multiple attempts of insertion and removal of flexible fiberoptic bronchoscope (alone or through an LMA and in the absence of ETT), leading to friction of bronchoscope against the vocal cords, or prolonged continuous use of rigid bronchoscope. There is literature supporting the prophylactic administration of IV steroids in a multidose regimen before planned extubation in decreasing the global incidence of laryngeal oedema and subsequent need for reintubation, with minimal adverse events.[21] However, other studies have shown prophylactic administration of steroids to be ineffective in reducing airway edema. [22] But, evidence of the real advantage of steroids is still controversial. During central airway interventions with rigid bronchoscope, we usually administer parenteral steroids to reduce the likelihood of laryngeal edema.

Anesthetic management of cases depends on the specific procedures and the patient's pathophysiology. Various planning issues deserve individualized consideration including:

- Location (OR vs Out-of-OR suite)
- Depth (sedation vs GA)
- Ventilation (spontaneous, intermittent apnea, Positive pressure ventilation, jet ventilation, etc.)
- TIVA vs Inhalation
- Plan for Fire Prevention and Response (if laser or electrocautery used)

- Plan for Distal Airway Obstruction (tumor, folded stent, extrinsic compression, etc)
- Plan for Massive Hemoptysis

Anesthetic management of commonly performed procedures:

1. RIGID BRONCHOSCOPY

Rigid bronchoscopy (RB) was initially performed under local anesthesia. Today, general anesthesia and appropriate ventilation method are recommended. The main indication for rigid bronchoscopy is the diagnostic and treatment of intra- and/or extraluminal obstruction of the airway. The beveled tip can help pass obstructing tumors in the airway and the large working channel can allow for passage of debrider instruments, laser equipment, balloons, stents and valves. The following interventional pulmonology techniques are usually employed through the rigid bronchoscope:

1.1) Tracheobronchial stenting:

Stent is a commonly employed procedure for the treatment of central airway obstruction. Currently, metallic stents are only licensed for malignant conditions, On July 29, 2005, the US Food and Drug Administration (FDA) issued a Public Health Notification recommending against the use of both covered and uncovered self-expanding metallic tracheal stents for benign lesions unless absolutely necessary. However, unlicensed use of stents has increased significantly because of either significant morbidity associated with other therapeutic options or exhaustion of other options. (Table 2)

Table: 2 Indications for stents Placement [23,24]
o Lung Cancer: small cell, non-small cell, metastatic, lymphoma
o Carcinoma esophagus
o Tracheobronchomalacia: Considered when patients are symptomatic and airway collapse > 60%
o Tracheo-oesophageal and bronchopleural fistulae
o Strictures: postintubation, post-traumatic
o Post anastomotic: tracheobronchial resection; heart, lung transplantation
o Inflammatory/Fibrous stenoses: post intubation, post-tuberculous, granulomatosis with polyangiitis, amyloidosis
o Laryngeal web/atresia
o Extrinsic compression: neoplastic, vascular oesophageal stenting, kyphoscoliosis, iatrogenic obstruction

The Montgomery T-tube was the first successful airway stent described in 1960s, which was designed for stenting the airway after repair of stenosis in the subglottic region. [25] It involved an external side limb protrusion through a tracheostomy. The first straight Intratracheal silicone

stents without side limbs were inserted in 1965 by Anderson and Egnud. [26] In 1990, Dumon presented the first distal airway stent which was used in the treatment of external compression of the main airway. [27] The Dumon stents were made of molded silicone and were relatively easy to place. These prevent tumor in-growth and cause minimal local tissue inflammation.
Broadly stents are divided into four categories [28] :
a) Silicone stents such as the Dumon stent or the Polyflex stent;
b) Metallic stents such as the Palmaz stent or the uncovered Wall stent
c) covered metallic stents such as the covered Ultraflex stent
d) hybrid stents such as the Dynamic stent (silicone stent with metallic rings)

Currently, Silicone (Dumon-type) stents are most popular and most frequently used worldwide. Their placement results in rapid relief of respiratory symptoms. They result in lesser inflammatory response and are easier to remove. Therefore, they can be deployed in any benign and malignant condition where expected survival is > 6months as well as palliation of critical respiratory obstruction.[29]They can be used for stenting of any structural stenosis of the trachea or bronchi except for tracheobronchomalacia. However, the silicon stents can only be deployed through a rigid bronchoscope and prior to their deployment, the airway needs to be dilated to a sufficient degree. They are predisposed to migration and have a smaller internal diameter to a similarly sized metal stent. This is one of the major limitations to the use of silicon stents as compared with metallic airway stents.

Metallic stents are self-expanding and made of metal (nitinol – nickel titanium alloy) in a mesh structure, which can be either uncovered or covered with silastic or polyurethane. Metallic stents with uncovered mesh become epithelialized after about 8 weeks. There is also high chance of tissue re-growth through the mesh leading to re-obstruction. Other complications include stent fracture, granulation formation and secretion inspissation. Metal stents can be deployed through both rigid or fiberoptic bronchoscope but are difficult to remove. They are primarily indicated in malignant conditions where predicted survival is limited.[24,29]

Anesthetic management:

Preoperative evaluation: Underlying lung condition affects the anesthetic management of the patient. Stent placement for the relief of an obstructed airway (tumor, stricture or stenosis) results in release of copious thick or even purulent secretions. Tracheobronchomalacia can become more severe when stenting induces frequent coughing episodes. Coughing and movement during procedure may result in total airway obstruction or worsening of SVC obstruction. Therefore, such issues should be anticipated and need of post operative ventilation should be explained to the patients beforehand.
Monitoring: Routine monitoring should be performed which include electrocardiography, non-invasive blood pressure, pulse oximetry and neuromuscular monitoring. Capnography is not reliable owing to inadequate ventilation. Alternatively, transcutaneous CO2 measurement, intermittent blood sample analysis through an eventual arterial line, aspiration of CO2 through the injector of HFJV after having provoked apnea may be used.[30,31] Depth of anesthesia monitoring is useful, as there is risk of intraoperative awareness during interventional RB.[32]

Anesthetic technique: Intravenous (IV) induction alongwith muscle relaxant provides the best operating conditions. TIVA is preferred over inhalational technique because it ensures continuous controlled delivery of anesthetic agent compared to an inhalation anesthetic-based technique even when there are ventilation leaks occur around the rigid bronchoscope [33]. It prevents operating room pollution by inhalational anesthetic agents and also avoids the risk of sedating operating room personnel. Propofol 100–200μg/kg per min and remifentanil 0.1–0.3mg/kg per min or fentanyl infusions 0.015-0.025 mcg/kg/min can be administered. Succinylcholine 1-1.5 mg/ kg can be administered in order to facilitate the passage of the rigid bronchoscope. Dexmedetomidine infusions have also been employed in pediatric rigid bronchoscopy in randomized controlled trials and it provides adequate anesthesia with less coughing and minimal respiratory depression or hemodynamic instability [34]. A maintenance dose of a nondepolarizing muscle relaxant, such as rocuronium 0.3-0.45 mg/kg or atracurium 0.08-0.1 mg/kg or vecuronium (0.04–0.06 mg/kg) IV repeated PRN, helps to maintain adequate levels of relaxation [35]. The 'pressor response' to rigid bronchoscopy can be attenuated, by the use of short acting agents like remifentanil/ fentanyl/ esmolol/ lignocaine. However, it critically narrowed airway, muscle relaxant administration should be considered very cautiously. In case of operator inexperience, muscle relaxant administration should preferably be avoided until a patent airway has been secured.

Ventilation strategy: The methods of ventilation [36] that are available include:

A) Apneic oxygenation

B) Spontaneous assisted ventilation

C) Controlled ventilation (closed system)

D) Manual jet ventilation

E) High-frequency jet ventilation (HFJV).

A) Apneic oxygenation: Some designs of rigid bronchoscopes feature a port on the direct conduit orifice, allowing intermittent airway instrumentation during apnea followed by instrument removal, sealing the port and positive pressure ventilation either manually or with a standard "anesthesia" ventilator delivering fresh gas via an anesthesia circuit connected to the side port. This technique relies on preoxygenation of the patient with 100% FIO2 with a brief period of time used to perform an intervention, followed by removal of the instruments from the bronchoscope and capping the proximal end, enabling the anesthetist to ventilate the patient. Given the limitations of this approach, apneic oxygenation has largely been abandoned by most centers except for very brief procedures in selected patients.

B) Spontaneous assisted ventilation: It is a total intravenous anesthetic technique whereby the level of sedation is closely titrated throughout the procedure to maintain spontaneous ventilation

by the patient. Supplemental oxygen is supplied through the rigid bronchoscope, and ventilation is maintained by the patient, with assistance from the anesthetist via bag ventilation attached to the rigid bronchoscope during periods of deeper sedation and apnea.

C) Controlled Ventilation (Closed System) An alternative to spontaneous assisted ventilation is controlled ventilation. In this technique, the rigid bronchoscope is used similarly to an endotracheal tube to provide inhaled anesthetic under positive pressure ventilation. This technique requires use of silastic caps on the ports of the rigid scope as well as packing the mouth with gauze to minimize air leaks from the uncuffed rigid tube. This technique can be challenging to perform due to the operating characteristics of common anesthetic equipment leading to circuit leaks and requirement of high fresh gas flows. Despite these challenges, controlled ventilation is the method of choice in some centers.

D) Jet Ventilation: Jet ventilation uses a high-pressure gas source that is applied to an open airway in short bursts via a small-bore catheter. Two modes of jet ventilation are currently available. The technique as originally described by Sanders[37] in 1967, uses a hand-operated valve (manual jet ventilation) connected to 100% oxygen and a pressure-limiting device to deliver gas to the patient at 50 psi or less with a respiratory rate usually in the range of 10 to 14 breaths/min. This mode of ventilation is especially useful in management of critical tracheal stenosis

E) High Frequency jet ventilation: The second mode of jet ventilation uses an automated system at respiratory rates substantially higher than physiologic (between 60 and 300 breaths/min, often termed HFJV) to allow for a nearly motionless operative field as well as freeing the anesthesiologist from ventilation during the procedure. The operator controls the applied pressure, respiratory rate, and inspiratory time to maintain adequate oxygenation [26]. HFJV is the most widely accepted alternative ventilation method in the context of interventional rigid bronchoscopy, creating high-quality and safe working conditions for the operator and the patient. [13] The injector catheter can be placed within the side arm of the bronchoscope. The HFJV advantages include the delivery of small respiratory volumes, often smaller than the dead space, limited movements of the diaphragm, the creation of a positive end expiratory pressure, which improves oxygenation by reducing the alveoli shunt, and the expulsion of laser generated smoke. Expiration occurs through the lumen of the bronchoscope and its surroundings The main risk of HFJV is pulmonary barotrauma, which occurs when expiration of the injected gas is impaired by upper airway obstruction. Other possible complications caused by jet ventilation include hypercapnia, hypertension, hypotension, hypoxemia and bronchospasm.

In the case of a metallic stent placement using a flexible bronchoscope, this can be done under laryngeal mask airway (LMA) or ETT in general anesthesia. The TIVA or inhalation anesthesia can be used. Sevoflurane causes least coughing and is preferred agent for this procedure. The patient may be able to breathe spontaneously during the procedure. Metallic stents can also be deployed using flexible bronchoscope without any airway conduit by experienced operators.

Complications: In cases of anterior mediastinal mass, there can be cardiovascular collapse at the time of induction or when the patient is made supine, because of tracheal obstruction. [5] Others include perforation of the airway (causing pneumothorax or pneumo mediastinum), airway obstruction caused by a malpositioned stent or edema and dissemination of pneumonia after relief of an obstruction in case of presence of localised distal infection. [38]

1.2) **Tissue resection and removal**: It includes Transbronchial Needle Aspiration (TBNA), line washings, lavage, debridement, resection, excision, and cauterization and cryoablation. The common aim of the removal of tissue is to relieve the obstruction or cancer or the acquisition of tissue to make a diagnosis. All of these techniques share the common complications of bleeding and perforation in the form of subcutaneous emphysema, pneumothorax or pneumomediastinum. Air can also embolize into the vascular system.

The type of technology used to manipulate tissues can determine the potential complications as well. Electrocautery can pose as a risk to the operating room personnel with the vaporization of carcinogens and the aerosolization of viruses. The argon beam coagulator has been associated with venous air (or argon) emboli, some of which have been seen to reach the left heart and coronary arteries. [39] Cryoablation has affected the nerve conduction of adjacent structures such as the vagus nerve, causing bradycardia.
Radiofrequency ablation also has been associated with nerve conduction as well as with local damage to instruments in adjacent structures; such as transesophageal echocardiography probes in the distal esophagus.

Brachytherapy, which involves the local implantation of radioactive implants, can lead to delayed hemoptysis and fistula formation.

Photodynamic therapy, which relies on the increased ability of neoplastic cells to incorporate and retain hematoporphyrin compounds, uses these compounds as photosensitizing agents. When exposed to monochromatic light via multiple bronchoscopic treatments, the neoplastic cells lyse. As such, hemoptysis can result from this extensive tumor necrosis. [40]

Anaesthetic Considerations:

Most cases of tissue washings and biopsies are performed through flexible bronchoscopy and require only conscious sedation. Certain biopsies, such as fine needle aspirations that require localization using endobronchial ultrasound (EBUS), usually happen under general anesthesia, which allows for a more precise movement of the ultrasound instrument and location of the fine needle. This general anesthetic often involves an LMA with either TIVA using propofol as described above or the continuous administration of an inhalational anesthetic, such as sevoflurane in 2–3%. However, moderate sedation is an equally well established and extensively used modality for performance of both linear and radial EBUS.

Another important but infrequently encountered clinical scenario is when bronchoalveolar lavage (BAL) is employed therapeutically for pulmonary alveolar proteinosis (PAP), a procedure known as Whole Lung Lavage. The BAL in this setting requires the administration of 10–50 liters of irrigating fluid, a procedure that takes several hours. Thus, the patient is

given general anesthesia and is intubated with a double lumen tube to accomplish lung isolation. The lungs are lavaged sequentially, with the ventilating lung as the nondependent lung and with the appropriate endobronchial cuff inflated to safeguard the ventilating lung. Warmed lavaging solutions are essential to prevent hypothermia.[40]

1.3) **Dilation of tracheal stenosis:**

Usual causes of tracheal stenosis are post intubation/post tracheostomy, neoplasm, trauma, chronic inflammatory disease, collagen vascular disease (such as granulomatosis with polyangiitis) and infection. The patient with tracheal stenosis often presents with obvious dyspnea at rest, audible stridor, and use of accessory muscles for adequate ventilation. Usually, these symptoms occur after an obliteration of at least 70% of the cross-sectional area of the airway. Dilatation can be performed with smooth round dilators, gradual dilation with ventilating bronchoscopes of increasing diameter, rigid bronchoscopes of increasing diameters or dilating balloons passed through flexible bronchoscopes. [41] In severe stenosis, a wire is passed across the narrowed area followed by a balloon advanced over the wire, carefully to expand the proximal portion of the stenosis first. Complications from balloon dilation include bleeding, airway perforation and fracture. Steroids can be used to minimize edema after these dilatations. They can delay the synthesis of collagen in the early stages of scar formation. However, they can also delay wound healing and cause cartilage resorption.[42] The smallest size rigid bronchoscope should be used initially for securing the airway. Then serial dilatation can be performed by rigid bronchoscopes of increasing sizes. Electrocautery knife is also a very useful accessory for initial incisions on the stenosis. Care should be taken during any heat generating procedure in the airways like electrocautery and laser as they carry the risk of 'endobronchial ignition'. To prevent the same, FiO2 should be kept below 40% while performing these procedures.

2. **FLEXIBLE FIBEROPTIC BRONCHOSCOPY:**

Conduction of Flexible fiberoptic bronchoscopy (FFB) usually requires minimal to moderate level of anesthesia alongwith topical anesthesia. In patients with limited cardiovascular or pulmonary reserve or anticipated prolonged procedures, deep sedation or GA may be required. According to British Thoracic Society (BTS) guidelines (2001), sedation should be offered to all patients undergoing FFB when there are no contraindications (Level B evidence).[43] The preferred mode of anesthesia for FFB is TIVA with LMA because it induces minimal pressor response and also allows for the examination of laryngeal apparatus. Benzodiazepines, opioids, and propofol have been preferable used for sedation during FFB owing to rapid onset and recovery and minimal respiratory depression or hemodynamic instability. Midazolam can be safely given iv in 0.5mg to 1mg increments at five minute intervals until desired level of sedation achieved. Commonly used opioids are fentanyl, alfentanil, remifentanil, meperidine and less frequently morphine. Studies comparing midazolam, alfentanil and combination have demonstrated that alfentanil group had lesser coughing but greater degree of desaturation

in combination group. However, there was no difference in the level of discomfort between the groups.[44]

Propofol provides dose dependent degree of sedation from conscious sedation to general anesthesia which can be administered as 0.5-1 mg/kg bolus followed by infusion at 25-75 mcg/kg/min for minimal to moderate sedation or 40-200 mcg/kg/min for deep sedation or anesthesia.[35] Propofol can also be administered as intermittent boluses, a single intravenous dose of 0.5–1.0mg/kg given slowly with top-up doses of 25–50mg every few minutes. Studies investigating the effect of the addition of alfentanil to propofol have shown greater respiratory depression in combination group than propofol alone.[45] Another study comparing propofol with a combination of midazolam and hydrocodone has demonstrated that propfol is as effective and safe as combined sedation in patients undergoing flexible bronchoscopy and represents a valid alternative to combined sedation with a benzodiazepine and an opiate.[46]

For topical anesthesia, it is recommended that total dose of lidocaine should be limited to 8.2 mg/kg in adults (approximately 29 ml of a 2% solution for a 70 kg patient) with reduction of dosage in the elderly or those with liver or cardiac impairment. The minimum amount of lidocaine necessary should be used when instilled through the bronchoscope.[43]

3. LASER BRONCHOSCOPY

Laser bronchoscopy is the delivery of laser energy via laser fibers passed through the working channel of standard bronchoscopes in order to treat a variety of endobronchial lesions.

Lasers suitable for laser bronchoscopy include the potassium titanyl phosphate (KTP), argon dye, yttrium aluminium pevroskite (YAP), Nd-YAG (neodymium-yttrium aluminium garnet) and diode lasers. The Nd-YAG laser is most widely used for airway resection[47] because depending on the amount of energy applied, its effects on living tissues (i.e. photocoagulation or vapourization) are predictable. It can be performed through flexible or rigid bronchoscopes. However, most surgeons prefer rigid bronchoscopy for all but the smallest lesions because the open tube allows for the simultaneous passage of the laser fibre, suction catheters, and forceps; adequate tracheobronchial toileting and the better management of hemorrhage within the airway.

Indications: The most common indication is inoperable cancer, either primary lung cancer (non small cell type) or endobronchial metastasis. Other indications include benign endobronchial tumors (e.g. papilloma, lipoma, leiomyoma), tumours of uncertain prognosis (adenoid cystic carcinomas, carcinoid tumours), and postinfectious or postintubation stenosis of the trachea or main stem bronchi.

Anesthetic Technique: Choice of anesthesia for laser bronchoscopy depends on the surgical technique. Rigid bronchoscopy usually demands general anesthesia, while fiberoptic bronchoscopy can be managed with either topical anesthesia and sedation or general anesthesia. For G.A., either inhalational or TIVA can be used; however TIVA is preferred over inhalational in laser surgery for two reasons. Firstly, there are leaks around bronchoscope which leads to inappropriate delivery of volatile anesthetics to the patient, and OR pollution. Secondly, inhalational anesthetics after flame exposure pyrolyse to potentially toxic compounds. ANSI Z136.3–2011 standard conservatively recommends not to use volatile anesthetics during airway laser surgery. There should be good coordination between the anesthesia and surgical teams so that need for an ETT, which tube type to use, the oxygen enrichment plan, and mode of ventilation can be discussed with surgeon. For jet ventilation catheter may be placed in either supraglottic or infraglottic position. For fiberoptic bronchoscope, either LMA or Laser resistant endotracheal tube can be used. In case of cuffed ETT, the cuff should be filled with saline rather than air whenever feasible. Methylene blue–dyed saline is another option which helps early identification of cuff breaches. Water-soaked sponges may be used which seal leaks of oxygen around an ill-fitting ETT cuff.

Laser Safety Precautions: These include: a) draping the patient with moist towels and eye pads in order to minimize risk of fires to patient's body b) Warning signs must be posted for persons entering the operating room. c) Laser goggles should be worn by all the persons in that area. d) Inspired oxygen concentration (FiO2) should be kept <40% to reduce the risk of ignition of flammable devices. [48]

4. THORACOSCOPY:

Medical thoracoscopy or pleuroscopy is a commonly performed pleural intervention by interventional pulmonologists that is different from Video assisted thoracoscopic surgery (VATS). It is usually performed as a single port technique.

Anesthetic considerations

Whereas simple diagnostic procedures can be conducted under local anesthesia by chest wall infiltration in combination with light sedation, more complex procedures that require sampling of tissue are best performed under regional (epidural, intercostals blocks) or general anesthesia. Most VATS procedures are performed under general anesthesia through one-lung ventilation (OLV) techniques using either double lumen tube or bronchial blockers or rarely, endobronchial tube. OLV allows for better exposure and guarantees a secure airway in the lateral decubitus position.[49]

SUMMARY and CONCLUSION :

Interventional pulmonology is a rapidly evolving field which includes variety of simple and complex procedures. It presents many challenges to anesthesiologists owing to sharing of airway with pulmonologists, already compromised lung condition of patients and dynamic nature of the procedures. A good preoperative evaluation in advance and anticipation of possible complications is essential for the successful anesthetic management. Choice of anesthesia whether general anesthesia or conscious sedation depends upon the type of procedure and patient's pathophysiology. TIVA is the preferred anesthetic technique for general anesthesia. Team approach, relying on good communication between surgeon, anesthesiologist and nursing staff is necessary for the success of a procedure. Anesthesiologist should be prepared with alternative airway management plan in case of failure of plan A. Ventilatory techniques should be planned and preparation should be done accordingly. Therefore, there is need to stay updated about the newly emerging IP procedures as well as various anesthetic and ventilation techniques.

CASE REPORT

Use of i-gel for laser ablation of a bronchial lesion

SUMMARY

The use of laser for airway lesions requires airway management. Usual options include special laser-resistant endotracheal tubes. The use of supraglottic devices have been described in the literature. Laryngeal mask airway carries the risk of cuff damage during the use of laser. i-gel is made of thermoplastic material and does not require air inflation and thus potentially reduce the risk of cuff rupture. i-gel use in laser surgeries has not been described in the literature. We present successful airway management in laser surgery for bronchial tumour using i-gel.

BACKGROUND

Light amplification by simulated emission of radiation (laser) has been used for treatment of benign (colon and rectal polyps) and malignant conditions (head and neck cancers, lung cancer, liver tumours). The use of laser for airway lesions requires anaesthesia and a secured airway. Various options for securing the airway include laser-resistant endotracheal tubes, wrapped tubes and jet injector. Laryngeal mask airway (LMA) has also been described for airway management.[1] LMA allows uninterrupted ventilation along with the use of fibreoptic bronchoscope through it.[1 2] In spite of the benefits, LMA carries the potential risk of cuff damage during laser use leading to inadequate ventilation and thus risk of hypoxia. i-gel has the specific advantages of non-inflatable cuff and the possibility of tracheal intubation through it, if required. Until now, i-gel use in laser surgeries has not been described in the literature. We describe successful airway management in laser surgery for bronchial laser ablation of a lung tumour using i-gel. Written consent was taken for publication of this case from the patient.

CASE PRESENTATION

A 61-year-old man presented with chief complaints of cough, haemoptysis and fever since 1 year. Contrast enhanced CT scan revealed heterogeneously enhancing mass lesion in lingular lobe of left lung, upper lobe collapse and multiple enhancing mass lesions in both lobes of liver. Positron emission tomography CT findings revealed somatostatin expressing disease in left upper lobe bronchus and liver metastasis. Flexible video-bronchoscopy performed under local anaesthesia revealed left upper lobe occluded by a vascular tumour along with purulent secretions. Bronchial washings confirmed the diagnosis of neuroendocrine tumour of left upper lobe bronchus.

DIFFERENTIAL DIAGNOSIS

In view of respiratory distress caused by proximal bronchus obstruction by tumour mass, laser debulking of tumour was planned. Pulmonary function test demonstrated moderately restrictive defect.

TREATMENT

In the bronchoscopic suite, after securing the intravenous access, intravenous hydrocortisone 100 mg was administered. Standard monitors including 5-lead ECG, pulse oximeter (SpO_2) and non-invasive blood pressure were attached. The patient was preoxygenated with 100% oxygen for 5 min at a flow rate of 15 L/min in 40° head up position. Anaesthesia was induced in head up position (40°) using intravenous fentanyl 100 µg, propofol 100 mg and rocuronium 60 mg. A continuous intravenous infusion of propofol 200–300 µg/kg/min was started. Lungs were ventilated using positive pressure ventilation. Three minutes later, rigid bronchoscope was inserted. On evaluation, growth was visualised in left upper lobe bronchus. Intermittent manual jet ventilation was started through side port (ventilating port) of rigid bronchoscope. Because of excessive air leak from and around the rigid bronchoscope, ventilation was ineffective. The pulmonary interventions of laser ablation required period of apnoeas and low inspired fraction of oxygen (FiO_2). So the ventilatory strategy was required to be changed. We modified our plan to perform ventilation through i-gel (supraglottic airway device) and perform laser ablation of tumour by inserting laser probe through flexible fibreoptic bronchoscope which is in turn inserted through the i-gel using an swivel connector (figure 1). I-gel (figure 2) of size 4 was inserted and positive pressure ventilation was initiated. The procedure was started with continued ventilation. During laser ablation, to minimise the risk of airway fires, FiO_2 was reduced to 0.30 and fresh gas flow was increased to 10 L to expedite clearance of oxygen in the airway. All routine laser safety precautions were followed including draping the patient with moist towels and eye pads, and antiglare glasses were worn by all the personnel. Flexible fibreoptic bronchoscopy was performed through swivel catheter mount and endobronchial neodymium-doped yttrium aluminium garnet (Nd:YAG) laser (23 W/cm^2, continuous mode) applied. During laser ablation, intermittent apnoea was provided. High-force suction was applied through bronchoscope to remove laser fumes. During desaturation episodes below 90% of oxygen saturation as assessed by SpO_2, use of laser was stopped and intermittent positive

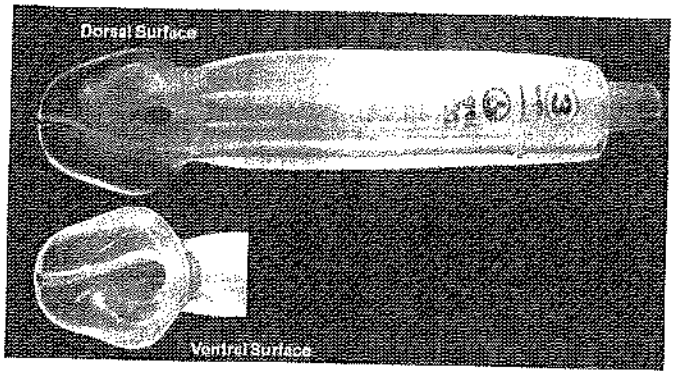

Figure 1 Use of i-gel during laser.

pressure ventilation was resumed. After adequate oxygenation, above steps were repeated until complete tumour carbonisation was achieved. Laser ablation lasted for 45 min and remained uneventful. After the procedure, the residual neuromuscular blockade was reversed with neostigmine 2.5 mg and glycopyrrolate 0.4 mg. Tracheal extubation was performed after adequate spontaneous respiratory efforts and when the patient regained consciousness.

OUTCOME AND FOLLOW-UP

Patient was shifted to high-dependency unit uneventfully for further management and observation. The patient was discharged on third postoperative day uneventfully.

DISCUSSION

Different types of lasers are used in clinical practice. Some lasers use a gaseous lasing media such as carbon dioxide, argon, krypton or helium–neon, while other lasers use solid rods of laser-passive material containing small quantities of ionic impurities, known as dopants. Dopants commonly used for their laser potential include chromium (as in the ruby laser), neodymium or holmium. Energy of an Nd:YAG beam is more widely disseminated, producing less vaporisation and more thermal coagulation. It can go deeper into tissue than light from other types of lasers, and it can make blood clot quickly. Nd:YAG lasers can be used through thin flexible tubes or optical fibres. Nd:YAG laser is used for lesions distal to larynx and for bulky, vascular endobronchial neoplasms because it can be used with a rigid bronchoscope or a flexible bronchoscope. In our case, we used it for debulking of neuroendocrine tumour of bronchus.

Laser surgeries are associated with specific hazards like airway fires, tissue and vascular perforation, eye injury, gas embolism, atmospheric contamination with laser fumes. Laser safety precautions should be used. Deposition of laser fume particulates in rat lung appears capable of producing interstitial pneumonia, bronchiolitis, reduced mucociliary clearance, inflammation and emphysema.[2 3] Nitrous oxide exothermically dissociates releasing heat and free oxygen. Nitrous oxide is thus a powerful oxidiser, and adding nitrous oxide as a diluent for oxygen is just as dangerous as having high FiO_2.[4] We avoided nitrous oxide for anaesthesia in our patient. Using an air–oxygen mixture appears to be acceptable. We used air–oxygen mixture to reduce the FiO_2 to prevent airway fires. Volatile anaesthetics when exposed to flame may pyrolyse to potentially toxic compounds.[5] Hence, we used propofol infusion rather than volatile agents to maintain anaesthesia.

Various airway management options are available which include jet ventilation with a modified Sanders venturi coupler, laser guard wrap around endotracheal tube, laser-resistant tubes like Norton, Laser-Flex tubes, Bivona Fome-Cuf and LMA. Studies with Nd:YAG laser has shown polyvinyl chloride, silicone and red rubber tubes to be vulnerable for damage because of ignition.[4–7] Covering of tubes with laser safe material such as copper and aluminium foil is an option, but wrapping is to be done very carefully with a 30% overlap, with no exposed tube, and adhesive used to stick foil is also flammable.[7] Commercially available laser-resistant tracheal tubes are expensive and their cuff is inflammable. Use of a metal endotracheal tube does not imply absolute protection from ignition as 50 W of Nd:YAG beam focused to 0.68 mm ignited a laser flex in 6 s.[6] Use of low FiO_2 (<30%) in lung with poor functional capacity poses a specific risk during laser surgery of a lung tumour as occurred in our case. Intermittent apnoea during use of laser also increases risk of desaturation. Jet ventilation is one of the modality in such situations but has the potential to produce barotrauma, pneumothorax or crepitus specially where in bronchial tumours require ablation. All these issues can be circumvented to large extent by using LMA. LMA has additional advantages of low frequency of coughing, better haemodynamic stability during insertion and improved oxygen saturation during emergence. LMA is an effective way to manage ventilation while simultaneously allowing unencumbered flexible bronchoscopic access for laser surgery.[1 6 7] Only few studies are performed about LMA in laser surgeries and use of i-gel is not reported yet.[7 8] The LMAs with air-filled cuffs are liable to get damaged with lasers.[9] Though silicone base cuff are reported to be more resistant to laser burns, but they are still not burn proof.[9] The use of saline for cuff inflation has been reported and may be of some use in laser surgery for prevention of cuff damage.[10] The occurrence of air leak from LMA damaged cuff would lead to difficulty in ventilation. i-gel has soft gel-like non-inflatable cuff which naturally positions itself over laryngeal framework providing a reliable perilaryngeal seal without the need of inflating cuff. It also provides conduit for intubation. It appears that the risk of cuff leak due to laser burn of the cuff should not be a concern as i-gel is made up of thermoplastic polymer (medical grade thermoplastic called styrene ethylene butadiene styrene) and does not require air inflation for making a good laryngeal seal. This technique would provide uninterrupted exposure to the airway lesion for ablation without compromising lung ventilation. The robust airway and gastric channel along with buccal cavity stabiliser of the i-gel would help in preventing potential of rotation

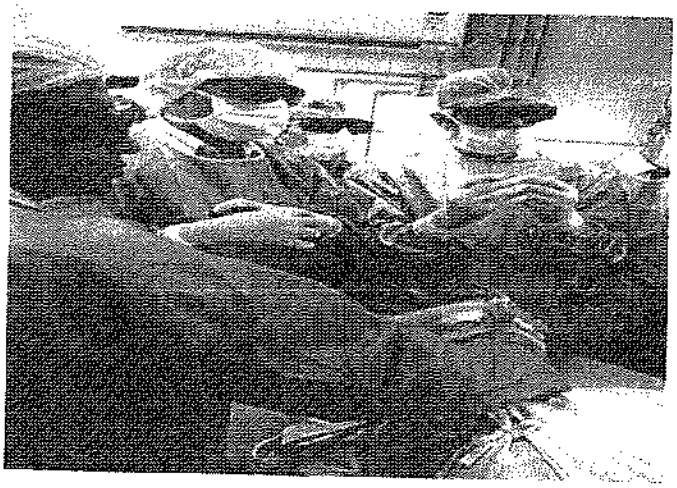

Figure 2 I-gel used for airway management.

and stability and its robust channel would prevent any accidental burn to it during the laser insertion or its removal. i-gel would easily accommodate the flexible fibreoptic scope for the laser procedures of the airway. The flammability of the i-gel itself has not been reported. The previous reported studies for use of LMA are usually with first generation device and has issues related to seal pressures, leak, prolonged positive pressure ventilation specially when airway pressure are high like in our case with bronchial lesions. The second-generation devices like i-gel have a better profile of its placement, better seal pressures and thus use of positive pressure ventilation effectively. The bronchial and lung tumours have increased airway resistance and thus require higher ventilatory pressures. Also, the better surgical condition with use of device would allow optimal tumour ablation and lesser chances of recurrence leading to airway compromise. The device not only provides continuous ventilatory support but also remains away from the surgical site of laser ablation and potentially lesser risk of fire. The conventional laser-resistant tubes are safer but would interfere in the laser ablation as they remain near to site of laser ablation and may interfere in optimal resection.

Learning points

- Patient undergoing laser surgery under anaesthesia remains challenging
- Airway management in patient requiring laser for bronchial tumour requires cautious selection of airway device.
- i-gel could be considered an airway management device for patients requiring neodymium-doped yttrium aluminium garnet (Nd-YAG) laser ablation of bronchial lesion in patient with lung cancer.
- Further testing may be warranted to evaluate the fire-resistant characteristics of the i-gel for its use during Nd-YAG laser surgery.

We conclude, the i-gel could be considered an airway management device for patients requiring Nd:YAG laser ablation of bronchial lesion in patient with lung cancer. It would be a good substitute for patients requiring laser ablation distal to glottis and other lower airway laser ablations. However, further testing may be warranted to evaluate the fire-resistant characteristics of the i-gel for its use during Nd:YAG laser surgery.

J Neuroanaesthesiol Crit Care 2020;00:1–2

Ankylosing spondylitis (AS) poses unique challenges to anesthesiologists owing to difficult airway and cardiorespiratory compromise.[1–3] We describe the anesthetic management of a case of AS with normal pressure hydrocephalus (NPH) for lumbar puncture (LP) followed by ventriculoperitoneal shunt (VPS) surgery.

A 68-year-old male weighing 65 kg, case of AS for 25 years, American Society of Anesthesiologists (ASA) grade III presented with gradually progressive slowness of gait and urinary incontinence for 5 months. Computed tomography scan of head was suggestive of hydrocephalus. Magnetic resonance imaging cervical spine revealed ankylosis of cervical vertebrae with arthrosis of the atlantoaxial joint (►Fig. 1). LP was performed in left lateral position with limited hip and knee flexion. 40 mL cerebrospinal fluid (CSF) was drained at a pressure of 12 mm Hg. Patient showed significant improvement in gait and a diagnosis of NPH was established. He was then posted for VPS the next day. Preanesthetic evaluation of the airway revealed restricted mouth opening (2 cm), Mallampati class IV, fixed flexion deformity of neck, and loss of cervical and lumbar lordosis. Breath holding time was 20 seconds and pulmonary function test revealed severe restrictive lung disease (forced expiratory volume in 1 second [FEV1] 34%, forced vital capacity [FVC] 33%, FEV1/FVC 101%). Risks of anesthesia pertaining to difficult airway and perioperative pulmonary complications were explained and consent for anesthesia was obtained, but patient refused for awake fiberoptic bronchoscopic (FOB) intubation. He was taught deep breathing exercises (DBE) and incentive spirometry (IS).

On the day of surgery, standard ASA monitoring was applied and a stack of pillows and gel-ring were placed under the head and neck in Trendelenburg position (►Fig. 2). After preoxygenation with 100% oxygen for 5 minutes, induction was done with 100 mcg fentanyl and 20 mg graded boluses (total 60 mg) of propofol to preserve spontaneous breathing. However, breathing became shallow and jerky due to backward falling of tongue and airway obstruction. Bag mask ventilation (BMV) was inadequate with nasopharyngeal airway (NPA) (size 8.0) but became possible with oropharyngeal airway (OPA). Due to failed attempt through oral FOB, plan was changed to nasal FOB. Glottic opening could be visualized only after pulling the tongue anteriorly and 7.5 mm endotracheal tube was advanced under vision into the trachea. Anesthesia was maintained with oxygen, air, desflurane, and atracurium. Because of nonmaneuverability of the neck, conventional surgical position with neck rotation was not possible and shunt was manipulated from the cranial burr (Kocher's point) in three passes. Patient was shifted to intensive care unit postoperatively. After the reversal of neuromuscular blockade, he was extubated when fully awake, obeying commands with adequate spontaneous respiratory efforts. DBE and IS were continued in the postoperative period. He was discharged on second postoperative day and was doing well with improvement in symptoms at 2 weeks' follow-up.

Discussion

Anesthetic challenges in management of the rare cooccurrence of AS with NPH has not been reported, and is probably the first case in literature.[2,3] It imposed array of difficulties ranging from technically difficult LP, airway hazards, and positioning issues.

Fibrosis of the spine made LP more complicated. One interesting finding in our case was difficulty in ventilation with NPA but not with OPA. This could be due to the malleable nature of NPA, and larger nares to epiglottis distance. It indicates that a standard size NPA can be shorter in case of fixed flexion deformity of neck. Direct and video laryngoscopy was not possible due to shaft getting struck to the chest and misalignment of oropharyngeal axis with laryngeal axis. Oral FOB was unsuccessful because of decreased oropharyngeal

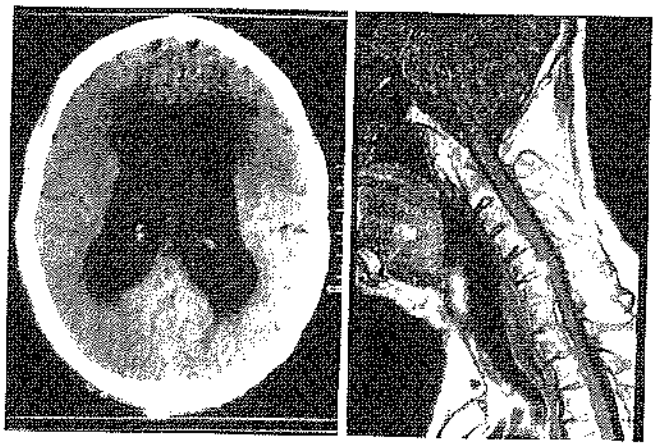

Fig. 1 Left side: Noncontrast computed tomography (NCCT) head (axial cut) showing hydrocephalus. Right side: Magnetic resonance imaging (MRI) cervical spine (T1 sequence sagittal) showing ossified vertebral column.

Fig. 2 Patient positioning (head low with pillows) to support head in fixed flexion deformity.

space and more acute angulation in approaching glottis via oral route, therefore nasal FOB was the better choice.[4] Lingual traction maneuver helped us in negotiation of FOB. Other airway supporting maneuvers like head tilt, chin lift, and jaw thrust were not possible because of probable ankylosis of the temporomandibular joint. Lung fibrosis leading to severe restrictive lung disease gave us only limited duration of apnea without desaturation for FOB. Adequate preoxygenation and oxygen insufflation through nasopharyngeal catheter during apnea period has been shown to increase the time to desaturation.[5] Careful positioning is imperative in AS because of high risk of spine fractures in osteoporotic bones.[6,7] Ideal positioning for intubation and procedure was not possible in our case due to fixity of the spine. A stack of pillows below the head helped to keep the head as in preoperative position.

To conclude, management of NPH with coexisting AS has its own challenges. Performance of LP to assess beneficence of a definitive CSF diversion procedure like VPS is difficult but necessary. OPA is a better choice for BMV. Nasal FOB with lingual traction while maintaining spontaneous respiration is the appropriate technique if the consent for awake FOB is not provided.[4] Restrictive lung disease and inappropriate posture add to the challenges. Preoperative lung expansion maneuvers and preparedness for the anticipated difficult airway is the key to successful management of this case.

Note

A written and verbal informed consent was taken from the patients' first degree relative (son).

ABSTRACT

Background: The supra scapular notch is the common site of supra scapular nerve entrapment causing supra scapular neuropathy. The supra scapular notch present in the superior border of the scapula is roofed by the Superior Transverse Scapular Ligament (STSL) which ossified in some scapulae and form supra scapular foramen.

Aim and objective: In present study we analyze, Morphological and Morphometric variations of supra scapular notch and ossified superior transverse scapular ligament in human dry scapulae.

Materials and Methods: In present study, we studied 136 dry human scapulae of unknown sex. We noted incidence of ossified superior transverse scapular ligament and Morphometric parameters analyzed.

Result: In present study we found 10 scapulae with complete ossified suprascapular ligament and 6 scapulae with partial ossified suprascapular ligament out of 136 dry human scapulae.

Conclusion: Ossified superior transverse scapular ligament is known factor for supra scapular nerve entrapment neuropathy so knowledge of incidence of STSL and anatomy of supra scapular region very useful for clinician, surgeons and orthopaedicians.

INTRODUCTION

The suprascapular notch is a depression or notch on the lateral part of the superior border of the scapula, medial to the coracoid process. This

structure is bridged by the superior transverse scapular ligament, which is sometimes ossified and the foramen which is thus completed, transmits the suprascapular nerve to the supraspinatus fossa [1].

The Suprascapular Nerve passes under the ligament and suprascapular vessels pass above the ligament. The Suprascapular Nerve gives motor nerve supply to the supraspinatus and infraspinatus muscles sensory nerve supply to the rotator cuff muscles and also supply the shoulder and acromioclavicular joint.

The suprascapular notch is frequently bridged by bone rather than a ligament, converting it into a bony foramen in some animals [2]. But in human, the STSL is sometimes ossified [1, 3].

The size and shape of suprascapular notch may be a factor in suprascapular nerve entrapment neuropathy because narrow notch has been found in patient with this neuropathy [4, 5].

The suprascapular notch is one of the potential site for compression of the nerve. Other causes associated with Suprascapular Nerve neuropathy include direct trauma, rotator cuff tear, ganglion cysts causing compression, sports injury due to repeated traction, variation of the SN morphology[6].

The presence of an ossified STSL may also pose a challenge during decompression of the suprascapular notch if the condition is not fully appreciated [7].

MATERIALS AND METHODS

In present study, we studied 136 dry human scapulae of unknown sex. This study carried out in Department of Anatomy of Pacific Medical College and Hospital and Pacific Institute of Medical Science Udaipur (Rajasthan). In this study damaged scapulae are excluded. We noted incidence of ossified superior transverse scapular ligament and following Morphometric parameters analyzed by digital Vernier caliper.

1. Vertical diameter of foramen
2. Transverse diameter of foramen
3. Area of supra scapular foramen
4. Superior maximal length of STSL
5. Inferior maximal length of STSL

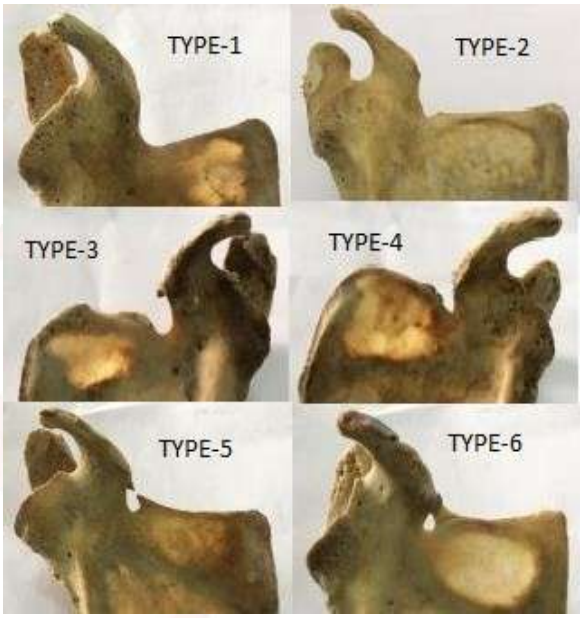
Area is count by area=π ×D1×D2/2

D1=Vertical diameter of suprascapular foramen

D2= Transverse diameter of suprascapular foramen

Also we classified suprascapular notch according Rengachary et al., Type I –complete absence of notch. Type II -wide blunted V shaped notch. Type III -symmetrical and U shaped notch with parallel lateral margins. Type IV -small V shaped notch. Type V- partial ossification. Type VI -complete ossified ligament

Fig. 1: Showing the different types of supra scapular notch.



RESULTS

In our study we used 136 dry human scapulae and measure various parameter, we found various types of suprascapular notch and shape of it noted in tables. We found 8% scapulae with complete suprascapular foramen and 5 % partial ossified suprascapular ligament. Other

DISCUSSION

In our study, we found the ossification of the STSL which convert notch in suprascapular foramen in 10 scapulae(8%) and partial foramen seen in 6 scapulae [5]. According to Paolo Albino et al,In Italian population complete foramen seen in 3.6 % of scapulae, same as in Kenyan population according to Sinkeet et al is 4%[9].

The suprascapular nerve entrapment may be due to traumatic or non-traumatic causes. The suprascapular nerve is commonly found to compress mainly at two sites, at the level of the suprascapular notch and the base of the scapular spine[10].

Compression and entrapment of the suprascaspular nerve at the suprascapular notch was first suggested by Kopell and Thompson and they also suggest Irritation of the SN gives rise to pain which is deep and poorly localized and because of this the cause of the pain and tenderness is difficult to discover in any individual and the muscle atrophy starts [11], According to ticker at al the shape of the suprascapular notch or the ossification of the STSL to predispose to suprascapular nerve entrapment.

Micha Polguj at al suggested that the mean area of the suprascapular foramen in the specimens with anossified band-shaped STSL is significantly smaller than in those with a fan-shaped STSL. Therefore, he confirm that band-shaped type of ossified STSL forms less space for the passage of the suprascapular nerve. Such an observation may explain why there is no increase in suprascapular nerve entrapment, even when the frequency of ossified STSL is very high, for example, 30.76% in the Brazilian population[12] According to Soni, G etal ,excessive movement of the shoulder exerts traction on the suprascapular nerve which leads to its compression-against the superior transverse scapular ligament[13]. Sandow & Ilic describe that specific volleyball movements and their implications at suprascapular nerve compression. The characteristically gestures e.g. of volleyball players as abduction associate lateral (external) rotation are factors that predispose the neuropraxis[14].

Gosk et al. state that peripheral nerves are highly susceptible to injury from stretching and compression. Both of these mechanisms result in nerve ischemia, edema, micro environmental changes, and conduction impairment [15].

Rengachary et al. first proposed an etiopathogenesis of suprascapular nerve entrapment known as the sling effect. It assumes that during maximum arm motioncause the irritates of nerve and induces microtrauma that can result in suprascapular[5]. Neuropathy, Most of studies showing incidence of suparascapular foramen but in our study we studied morphometric analysis of suprascapular notch and its suprascapular foramen knowledge is very important for decompression of suprascapular nerve.

Incidence of suprascapular foramen and STSL in other study are shown in table 3.

CONCLUSION

Ossified superior transverse scapular ligament is known factor for supra scapular nerve entrapment neuropathy so knowledge of incidence of STSL and anatomy of supra scapular region very useful for clinician, Surgeons and Orthopaedicians for diagnosis and treatment.

Abstract

The liver is the largest abdominal visceral organ, occupying a substantial portion of the upper abdominal cavity. The liver has four lobes, Caudate lobe is a separate and distinct liver lobe. It is located on liver at the posterior surface. The caudate lobe has two portions joined by a narrow parenchymal bridge that is called the caudate isthmus. Caudate lobe also has its separate blood supply and biliary drainage. The complexity of liver function and its importance in body homeostasis has encouraged this study of morphology and variations of caudate lobe to better the diagnosis and analysis of clinico-pathological conditions. For present study 100 cadaveric livers were obtained. Caudate lobe was studied on various parameters such as shape, size and dimensions. Various measurements were taken and data was analyzed using descriptive statistics and relational statistics. 'Z' test was computed to find out the association between the parameters of the present study and the studies of similar background. It was found that majority of the caudate lobes in all livers are rectangular 67 (67%) in shape followed by pyriform 21 (21%) and irregular 12 (12%) shaped. The average transverse diameter of caudate was measured 28.69 ± 7.73.The average longitudinal diameter of caudate lobe was measured 54.67 ± 10.73. A sound knowledge of the normal and variant liver anatomy is a prerequisite to having a favorable surgical outcome and commonly occurring variations assumes even more significance in the era of diagnostic imaging and minimally invasive surgical approaches.

Keywords: Liver, Caudate Lobe, Surgical resection, Harbin's measurements.

INTRODUCTION

The liver is one of the largest abdominal organs, occupying a large portion of the upper abdominal cavity. It is present in right hypochondria and epigastrium, and extending into left hypochondria as far as left lateral line [1]. The liver has four lobes; gross anatomical appearance of the liver has been divided into the right, left, caudate and quadrate lobes by the surface peritoneal and ligamentous attachments [2]. Various ducts, veins and arteries are present on the surface of the lobes that allow the inflow and outflow of fluids [3]. Caudate lobe is a separate and distinct liver lobe. It is located on the posterior surface of the liver between the groove for inferior vena cava (IVC) to the right and fissure for Ligamentum venosum to the left and on the anterior side of porta hepatis. The caudate lobe has two portions joined by a narrow parenchymal bridge called the caudate isthmus. This lobe also has separate blood supply and biliary drainage [4].

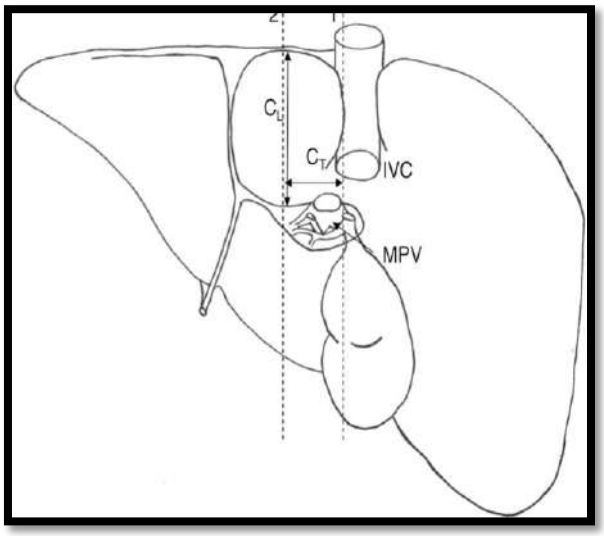
In man, the liver is essential for survival since there is currently no artificial organ or equipment that has the capacity to compensate for the absence of liver function [5]. The complexity of liver function and its importance in body homeostasis has encouraged many anatomists to study the morphological features of the organ in considerable detail [6]. For the surgeons it is of paramount importance to have clear knowledge of the structure of the normal organ and its variations during the period of growth and ageing.

MATERIAL & METHODS

The study was conducted on 100 cadaveric livers obtained from the Department of Anatomy, Baroda Medical College, Gujarat, India. Any liver from cadavers with previous history or appearance of cirrhosis, metastatic disease or other liver pathology and any cadavers with previous history of or an appearance suggestive of any trauma disease or abdominal surgery were excluded from the study. The approval was obtained from the Institutional Ethics Committee for Human research, Medical College Baroda, Gujarat prior to the commencement of the study. The liver specimens collected were allotted numbers from 1 to 100. The numbering to the specimens were given using synthetic thread and

laminated tags. Anatomy of the caudate lobe was studied after defining and cleaning lesser omentum covering its two of the four margins [7].

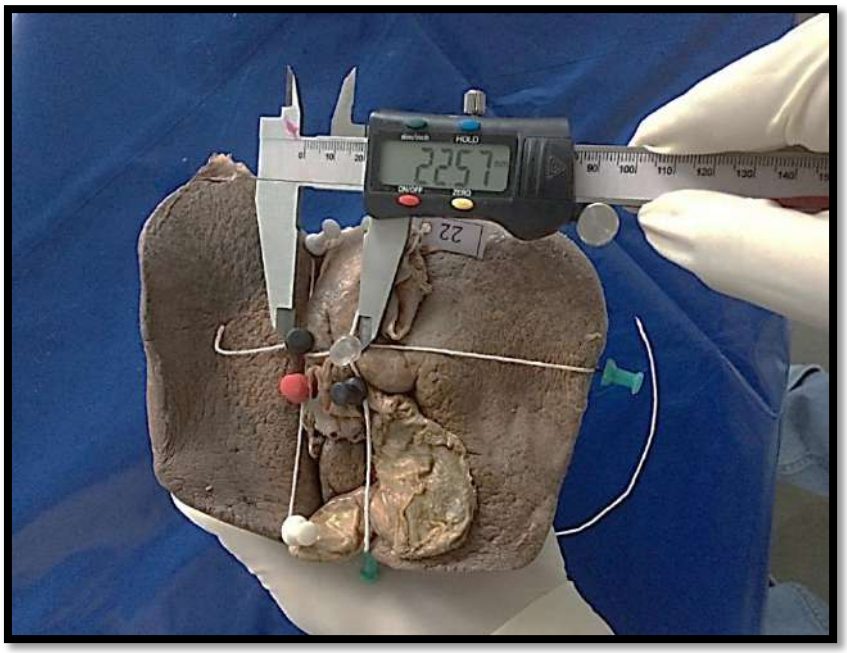
Each liver was placed in the anatomical position to facilitate visualization of the diaphragmatic and visceral surfaces, and morphometric measurements were performed with the aid of cotton threads and digital Vernier caliper in mm. Each liver was examined on three different occasions by the examiner and the mean of the three readings was derived. A line, L1 is drawn through the right lateral wall of the main portal vein. Another line, L2 was drawn parallel to L1 at the most medial aspect of the caudate lobe. Another line, L3 was drawn perpendicular to lines 1 and 2, midway between Main Portal Vein and the inferior vena cava, and extended out to the lateral margin of the right lobe. For consistency, in the present study the most medial aspect of the caudate lobe was considered as the medial extent of the transverse diameter of the porta hepatis in all livers [8, 9].



Visceral surface of the liver, demonstrating the greatest longitudinal diameter of the caudate lobe (CL) measured supero-inferiorly. CT transverse diameter of the caudate lobe, IVC Inferior Vena Cava, MPV Main Portal Vein

CT – Transverse diameter of caudate lobe: Measured from the most medial margin of the caudate lobe to the right lateral wall of the portal vein.

CL – Longitudnal diameter of caudate lobe: Measured at the level of the greatest longitudinal extension of the caudate lobe.



Transverse diameter of the caudate lobe measured on L3 between L1 and L2

The distinct morphological characteristics observed were recorded on individual data sheets in a form appropriate for posthumous analysis [3].

The data was analyzed using descriptive statistics (frequency, percentage, mean, median, standard deviation, skewness and kurtosis) and relational statistics i.e.'Z' test. Z' test was computed to find out the association between the parameters of the present study and the studies of similar background [10].

OBSERVATIONS AND RESULTS

In the present study, a total of 100 embalmed human livers evacuated were studied, 18 livers (18%) were normal in their external appearance. However, 82 (82%) specimens showed anomalies in lobes, fissures, shape and size of lobe. On examining the caudate lobe it was found that majority of the caudate lobes in all the livers are rectangular 67 (67%) in shape followed by pyriform 21 (21%) and irregular 12 (12%) shaped.

Table-1: Shape of Caudate lobe

Shape of Caudate lobe		
Type of Shape	No. of Liver specimen	Percentage %
Rectangular	67	67
Pyriform	21	21
Irregular	12	12

The average transverse diameter of caudate was measured 28.69 ± 7.73, while the values ranged between 14.68–50.81. The mean is more than median and $S^3 > 0$, which indicate positively skewed distribution of data because observations tend to concentrate more at the lower end of the possible values. The distribution is more spread out than normal as kurtosis is less than 3 (platykurtic). The average longitundal diameter of caudate lobe was measured 54.67 ± 10.73 and the values ranged between 35.41–74.24. The mean is less than median and $S^3 < 0$, which indicate negatively skewed distribution of data because observations tend to concentrate more at the higher end of the possible values. The distribution is more spread out than normal as kurtosis is less than 3 (platykurtic).

Table-2: Morphology of caudate lobe

Parameter	Mean (SD)	Median	Skewness (S^3)	Kurtosis (S^4)
Transverse Diameter (CT)	**28.69 (7.73)**	**27.97**	**0.75**	**0.15**
Longitudinal Diameter (CL)	**54.97 (10.73)**	**56.23**	**-0.91**	**-1.07**

Table-3: Morphology of Caudate Lobe comparing with other studies

Authors	Present study	Sahni *et al.*, [11]	Ahidjo *et al.*, [12]	Chavan *et al.*, [13]	Arora *et al.*, [14]	Sagoo *et al.*, [15]	Reddy *et al.*, [16]
Sample size	100	138	-	50	36	50	80
Transverse Diameter of caudate lobe	28.69±7.73	32.7± 7.6	34.1± 6.5	25.0	27.0	27.4± 12.2	25.4
Longitudinal diameter of caudate lobe	54.97± 10.73	-	-	81.5	50.3	57.4± 14.1	47.8

DISCUSSION

An attempt was made to find out the variations in the shape and size of caudate lobe to aid into clinical and surgical applications.

The findings of the present study for shape of caudate lobe are 67 (67%) rectangular, 21 (21%) pyriform and 12 (12%) irregular. Sahni et al. studied 200 specimens of liver. They observed that 189 (94.5%) were rectangular, 9 (4.5%) pyriform and 2 (1%) irregular. Sagoo et. al. also studied 50 specimens of liver for Northwestern Indian reported 45 (90%) rectangular, 03 (6%) pyriform and 02 (4%) irregular shapes of caudate lobe. In the Present study the average transverse diameter of caudate was measured 28.69 ± 7.73, while the values ranged between 14.68–50.81 and the average longitundal diameter of caudate lobe was measured 54.67 ± 10.73 and the values ranged between 35.41–74.24. Such measurements were compared with the studies done in the past as shown in Table-3.

CONCLUSION

A sound knowledge of the normal and variations in liver anatomy is a prerequisite to having a

favorable clinical outcome. The commonly occurring anatomical variations in liver have even more significance in the era of diagnostic imaging and minimally invasive surgical approaches. The absence of normal fissures or the presence of additional lobes might lead to confusion on a radiological diagnosis of a liver disorder. The modern era of imaging and minimally invasive liver surgeries have started after the intrahepatic segmentary anatomy was classified. It is very important on the part of both the radiologists and surgeons to have a thorough knowledge of the normal anatomy and the commonly occurring variations of this organ. The success of liver transplantation points towards an increase in liver operations in the future.

ABSTRACT

Background: *Cephalic index exhibits sexual differences and different shapes of head. This information will be highly important for Plastic surgeons, Forensic Scientists, Anatomists, Human Biologists, Criminologists & Physical Anthropologists.*
Materials & Methods: *The present study was observed on 200 living subjects of Jhalawar district Rajasthan (100 male and 100 female) of 18 to 25 years in the year of 2013 with the objective to study the sex differences and food habitual in cephalic index. Cephalic index was investigated with the help of head length and width with the use of spreading caliper.*
Results: *The study showed that mean cephalic index was higher in females than in males.*
Conclusion*: Predominant head type was dolicocephalic in both sexes.*

Key words: *cephalic index, dolicocephalic, vegetarian, non-vegetarian*

INTRODUCTION

Anthropometry is a technique of measuring the human body in terms of dimensions, proportions, and ratio such as those provided by cephalic index for determining various head. Cephalic index is the most frequently investigated craniofacial parameters as it utilizes the length and breadth of the head which are useful indices in the study of secular trend[1,2] Body dimension are affected by ecological, biological, geographical, racial, gender and age factors as quoted by Imami.[3] Lifestyle, nutrition, intercaste marriage, environment, geographical variation and ethnic composition of population lead to change in body dimension and require regular updating of anthropometric data. Ever since the human life came to existence, constant changes are occurring in morphological appearance.[4] Cephalic index is calculated as Maximum head breadth / Maximum head length x 100.[5] On basis of cephalic index head shapes classified four international categories Doliocephalic (CI up to 74.9), Mesocephalic (CI 75-79.9) Brachiocephalic (CI 80-84.9), Hyperbrachiocphalic (CI > 85).[6]

We in our study include Jhalawar region which is one of the biggest parts of Rajasthan. As no research, has been conducted in this area, we tried to establish and compare Cephalic Index of 18 to 25 years age of students of Jhalawar district (Rajasthan) with available data of various Indian populations. This study useful for Plastic surgeons, Forensic Scientists, Anatomists, Human Biologists, Criminologists & Physical Anthropologists.

Source of Support: Nil, **Conflict of Interest:** None

This descriptive and cross sectional research was done on 200 students (100 Males and 100 Females). Students were selected because of the easy availability. The age of the students ranged from 18 to 25 years. The study was conducted on the Govt. PG College and Govt. Girls PG college Jhalawar (Raj.). All the measurements were taken with the subject sitting in chair, in relaxed condition and head in anatomical position. The method used for assessing the cephalic index is Hrdlicka's method.[7]

The head length from glabella to inion will measure with the help of spreading caliper. The head breadth will measure as the maximum transverse diameter between two fixed point.

Cephalic Index = Head Width/ Head Length x100

RESULTS

A total 200 adults were studied out which 100 (50%) were male and 100 (50%) were female. The male subject was divided in to out of 100; vegetarian male – 57 (57%) and non-vegetarian male-43(43%), and female subject were divided in to out of 100; vegetarian female-83 (83%) and non-vegetarian female-17 (17%). The study subjects were aged between 18 years to 25 years and Mean Cephalic Index was 74.23(SD=2.68; p=0.393).For Males, Mean Cephalic Index for Male was 74.07(SD=2.31; p=0.617).For Females, Mean Cephalic Index for Female was 74.39(SD=3.00; p=0.568).For Vegetarian Males Mean Cephalic Index was 13.73 (SD=.604).For Non-vegetarian Males Mean Cephalic Index for Non-vegetarian males was 74.20 -(SD=2.34).For Vegetarian males, Cephalic Index for Vegetarian females was 74.31 (SD= 3.091). For Non-vegetarian Females, Mean Cephalic Index for Non-vegetarian females was 74.77 (SD=2.581). Collected data of present study was statistically analysed. The observations and results are presented in the tabular form.

Table 1: Cephalic index of the study subjects according to gender

Cephalic index (cm)	M	F	Total (%)	Cephalic index (cm)	M	F	Total (%)
68.01 to 69	0	3	3 (1.5%)	75.01 to 76	14	8	22 (11%)

DISCUSSION

The variations in cephalic indices between and within population have been attributed to a complex interaction between genetics and environmental factors. In present study the mean cephalic index in males was 74.07 and in females 74.39. So the dominant type of head shape in male was dolichocephalic (60%) and in female was 56%. The findings of dolichocephalic was similar to study done on (Anitha et al, 2011)[4] North Indians in which 40.6 % was dolichocephalic and 15.6% was hyperdolichocephalic but

the percentage was more than this study & the mean cephalic index is more in previous study. North and central Indian population have Dolichocephalic predominance (Singh & Bhasin, 2006). This is in agreement with the present study.

In our study, dominant type of head shape in males was dolicocephalic (60%) and mesocephalic (39%) and the mean cephalic index was 74.07 (doliocephalic). This finding of dolicocephalic was similar to study done on Indian males (Bhatia *et al*., 1995) in which 58.5% of population was dolicocephalic, but not similar with the study by Shah & Jadhav[9] in Gujarati (41%) which showed Mesocephalic head shape was common. The dolicocephalic shape was a rare type found in 7% in Indian gujarati (Shah & Jadhav).[9]

The similar studies were conducted in different groups and Cephalic index was found to be different for different groups due to genetics and geographical factors. The value of mean cephalic index (males & females) in present study is lower as compared to other study however Bhils of central india, Haryanvi population have value close.[14]

CONCLUSION

The result of present study showed that all male and female of Jhalawar region students of age group of 18 years to 25 years of colleges of Jhalawar District (Rajasthan) are Doliocephalic according to classification based on cephalic index.

There was a significant difference ($p < 0.393$ & difference 0.32) between cephalic index of male and female of Jhalawar region. Thus, we can conclude that cephalic index of the female is some point higher than the male in Jhalawar region population.

There was a significant difference ($p < 0.617$ & difference 0.23) between cephalic index of Vegetarian male and Non-vegetarian male of Jhalawa region. Thus, we can conclude that cephalic index of the Non-vegetarian male is 0.23point higher than the Vegetarian male in Jhalawar region population.

There was a significant difference ($p < 0.568$ & difference 1.8) between cephalic index of Vegetarian female and Non-vegetarian female of Jhalawar region. Thus, we can conclude that cephalic index of the Non-vegetarian female is 1.8 point higher than the Vegetarian female in Jhalawar region population.

ABBREVIATION – CI – Cephalic Index

ACKNOWLEDGMENT

The author and co-authors acknowledge the support given by the Department of Anatomy, Jhalawar Medical College, Jhalawar (Raj.) India. The participants of Govt. PG College and Govt. Girls PG College Jhalawar (Raj.) and other individuals to ensure the successful completion of this study.

ABSTRACT

Background: *Human body is made up of framework of variety of bones and make human body Bone is core structure of the human skeleton and form the framework of the human. During embryological and fetal life arteries enter into long bone through nutrient foramen and entry into medullary cavity, which is, require for growth long bone. Various surgical procedures like fracture reduction, bone grafting and joint replacement require sufficient knowledge of nutrient foramen and nutrient artery.*
Aim: *The Aim of the present study is: (A) To identify the position, number & direction of diaphyseal nutrient foramina of Tibia. (B) To identify any variations in number, location and position of diaphyseal nutrient foramina of tibia. (c) calculate the foramina index by Hughes formula.*
Materials and methods: *Present study was conducted on 100-dried Human Tibia with unknown age and sex, which was taken from the anatomy department of Geetanjali medical college & Hospital Udaipur and Pacific medical college & hospital, Udaipur and marked number on it. Morphological and pathological abnormal bones excluded from study. Help of vernier caliper and fine gauge needle, we observed location and distance from proximal end, number and direction of nutrient foramen and calculate foramina index.*
Results: *In present study we found single foramen present in 80 bone, Double foramen present 18 bone and in 2 bone there was triple foramen at different level. According direction: In upward direction of foramen found in 1 bone, horizontal direction found in 3 bone and most of bone have downward direction. According location: In most of bone Nutrient foramen was situated on posterior surface except in four bones where it was situated on lateral surface and In 66 bone Nutrient foramen present in upper 1/3 of bone except 34 bone where it present in middle 1/3.*
Conclusion: *In present study we found, Nutrient foramen was located mostly on the posterior surface and direction was downward. Nutrient artery is very important for blood supply of long bones. Therefore, it is very important for surgeons to have sound knowledge of precise morphology and morphometric of nutrient foramen*

Keywords: *Nutrient foramen, Nutrient artery*

INTRODUCTION

Long bone of human body gets nutrition mainly from 3 artery 1) Nutrient artery, 2) Periosteal artery, 3) Epiphyseal Artery. But main source of blood derived from Nutrient artery, which supply diaphysis and metaphysis. During its course Nutrient artery first enters into the bone through nutrient foramen.[1] According to various cadaveric studies the Nutrient foramen is directed away from the growing end of in Adult the bone.[2,3] In lower limb leg bone, nutrient foramen is generally directed downwards because upper end is growing end, as it fuses with shaft in the 16 and 18 year in female and males respectively. While lower-end fuses with the shaft at about 15th year in females and 17th year in males. For tibia Nutrient artery derived from a branch of posterior tibial artery. Rarely it may arise from popliteal artery or anterior tibial artery.[3] Nutrient Artery is very important and vital for early embryogenic development and maturity of bone.[3] Nutrient artery provides 70-80% of blood supply to the long bones of human and if any deterioration in blood supply of long bone during early child and adult life, it may affect the growth of long bone if injury during fracture reduction, bone grafting

and joint replacement lead to ischaemia of long bone resulting into less vascularisation of diaphysis, metaphysis and growth plate.[4] Because of this orthopedic and surgeons to have well knowledge of nutrient foramina before go to surgery to prevent catastrophic damage artery. The tibia is commonly involved in several surgical procedures like bone grafting, the knee replacement, external and internal fixation of fractures and bone resection for tumours.[5,6] Present study was conducted for knowledge of morphology and morphometric of nutrient foramen on tibia.

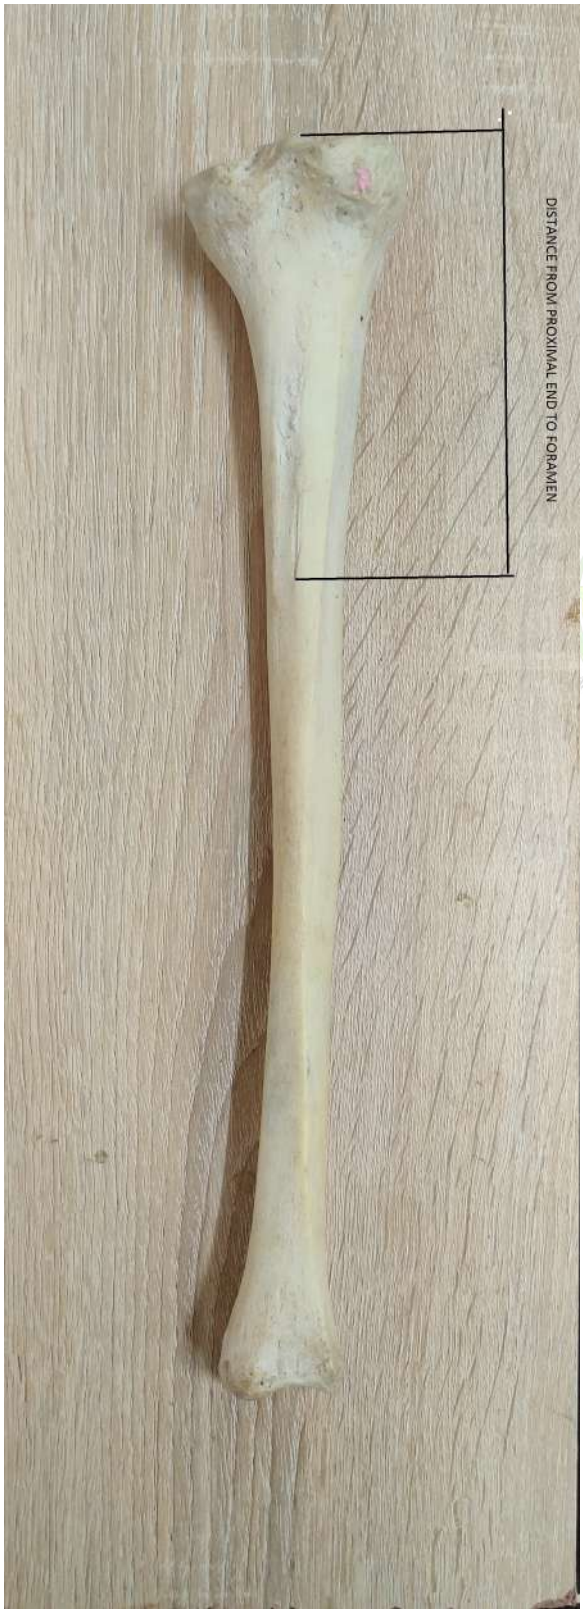

Fig 1: Showing distance from proximal end of Tibia to Nutrient Foramen

METHODS

The present study included 100 dried tibia bones with unknown age and sex, which was taken from the anatomy department of Geetanjali medical college & Hospital Udaipur and Pacific medical college & hospital, Udaipur and marked number on it. Morphological and pathological abnormal bones excluded from study.

Help of vernier caliper and fine gauge needle, we study 53 right sided tibia and 47 left sided tibia. We study A) Number of foramen present on bone. B) Location of foramen present on which surface. C) Nutrient foramen direction. D) Total Length (TL) of Tibia. E) Distance (PF) from proximal end of tibia. F) With Help of Hughes formula, we calculated Foramina Index.

Number, Location and Direction observed macroscopically with help of gauge needle and osteometric board was noted. Total length (From the Upper margin of the medial condyle and lower end of medial malleolus and Distance of Foramina measured from proximal end of Tibia.

Foramina Index: with help of Hughes formula, we calculated our data.

Foraminal index = PF/TL×100

According to index,

Position of foramen was determined Accordingly,

A) Foramen is in the Lower 1/3 of the bone if Index >66.66
B) Foramen is in the Middle 1/3 of the bone if Index between 33.33 to 66.66
C) Foramen is in the Upper 1/3 of the bone if Index < 33.33

RESULTS

In present study we found single foramen present in 80 bones, Double foramen present 18 bones and in 2 bones there was triple foramen at different level. According direction: In upward direction of foramen found in 1 bone, horizontal direction found in 3 bone and most of bone have downward direction. According location: In most of bone Nutrient foramen was situated on posterior surface except in four bones where it was situated on lateral surface and in 66 bone Nutrient foramen present in upper 1/3 of bone except 34 bone where it presents in middle 1/3.

Table 1: Showing average Total length, distance from proximal end and number of nutrient foramen of Tibia.

	Total length Tibia (TL) (Average in cm)	Distance from Nutrient foramen from Proximal end of Tibia (PF) (Average in cm)	Number of foramen present on bone		
			Upper 1/3	Middle 1/3	Lower 1/3
Rt	36.5	12.1	35	18	0
LT	36.8	11.92	31	16	0

Table 2 Showing direction and location of Nutrient foramen

	Number foramen			Direction of Foramen			Location of foramen (surface)	
	Single	Double	Triple	Downward	Upward	Horizontal	Posterior	Lateral
Rt	42	9	2	52	1	3	56	4
Lt	38	9	0	44	0	0	40	0

DISCUSSION

Long bone in human is mainly supply by Nutrient artery which enter into bone through nutrient foramen then it divided into ascending and descending branch then supply rest part of

bone and provide nutrients to bone which require for growth of bone. The entry point is present in diaphysis that why this artery also called diaphyseal artery. For any fracture surgery and reconstructive surgery there have very caution about this artery and its course. Any injury to nutrient artery during surgery which cause the catastrophic event which very dangerous to bone growth in child. Because of this depth knowledge of anatomy of this artery is very important for orthopedic and surgeon.

In our study, we studied many parameters.

Number of foramen: In present study we found single foramen in 80 bone and most authors study found same, our study noticed Double nutrient foramina were found in 18 numbers of bones. Zahra SU et al. found around 4.5 % bone have double foramen,[7] Seema et al. reported 10% bone have dual foramen,[8] other author like Roul B et al. and Udaya P et al., noted 16.2% and 23.8 % of double foramina in bone which higher than other study.[9,10] We have found triple foramen in our study was only 2 % it also less number in other study like Swapna SA and Udaya P found 3.80% and 2.70% in their studies.[10] In our study we have not found any bone without nutrient foramen but few study found absent nutrient foramen like Joshi P, Prashanth KU and Gupta RK observed there is no nutrient foramen in 6%, 1.4% and 6.20% of tibia respectively.[11-13] In this case blood supply carried by periosteal vessel.[13]

Direction of foramen: There are changing in direction of nutrient foramen during embryological and after birth. Starting period of life nutrient arteries going in caudal direction toward growing end but in long bone growth is different because of this nutrient artery is directed away from the growing end.[4] In our study mostly all bone has nutrient foramen direction was downward, only less 1 and 3 % bone have upward and horizontal direction. Also, Mazengenya P and Faremore MD, noted direction of foramen upwards in 0.6% and 1.7% of tibia in South Africans population.[14]

Location of Foramen: In our study, most bone's nutrient foramen was found on posterior surface the tibia 96 % except in 4% bones where it was found on the lateral surface, many textbooks and studies of various of authors also have noted the location of foramen on posterior surface in most of the bones but some author found on medial surface like Kamath V et al., found foramen on medial surface in 2.82% of bones.[6] Hiren Chavda found in 87.14% of bones, foramina were located lateral to vertical line; in two bones it was medial to vertical line and in four bones on the vertical line.[1] Seema et al., and Collipal E et al., found 3.77% and 4% of tibia having nutrient foramen on the soleal line.[8,15]

Total Length of tibia (TL): In our study we found total length of tibia was 36.5 and 36.8 on rt and Lt side. Hiren Chavda was found to be 35.1±2.3 cm on right side and 35.2±1.96 cm on the left side.[1] In black South Africans and white South African length were 38.44 cm and 37.12 cm observed by Mazengenya P and Faremore MD.[14] In Turkish population length of tibia was 35.8 cm noted by Kizilkanat E and Pereira GAM et al., found it to be 37.31 cm .[16,17]

Average distance of nutrient foramen from proximal end (PF); In present study we found there was distance between proximal end and foramen was 12.1 and 11.92 on Rt and Lt side respectively. According to Hiren Chavda observation, the distance was 11.8±1.93 cm on right side and 11.8±2.28 cm on left side.[1] Ankolekar VH et al., found distance was 13 cm and 13.4 cm on the right and left side respectively.[2] Joshi P and Mathur S, found on Rajasthani population, this distance was 14.53±3.77 cm on right side and 14.0±2.99 cm on left side.[11]

Distance of nutrient foramen from proximal end (PF): Average distance of nutrient foramen from proximal end in our study was 12.1 cm and 11.92 cm respectively on Right and left side. Hiren Chavda et al., observed in their study was 11.79 cm and 11.8 cm on the right and left side respectively.[1] Joshi P and Mathur S, found distance was as 14.53±3.77 cm on right side while 14.0±2.99 cm on left side.[11]

Foraminal Index (FI):

In our study was found to be it was in the middle 1/3. Gupta RK and Gupta AK also observed similar findings in Gujarati population.[13] Vadhel CR et al., in their study on Gujarati population found occurrence of nutrient foramen on upper 1/3 in 99.5% of bones, which was higher than the present findings.[18] Mohan K et al., found it on upper 1/3 in 42% of bones while in 52%, it was on middle 1/3.[19] No foramen was found in the lower 1/3rd of the tibia. Kamath V et al., reported nutrient foramen in upper 1/3rd in 74.65% of bones and in middle 1/3rd in 25.35% of bones.[6] Pereira GAM et al., and Mazengenya P and Faremore MD, in their studies also found nutrient foramen more commonly on upper 1/3rd more than on the middle 1/3rd.[14,17]

CONCLUSION

In present study we found, Nutrient foramen was located mostly on the posterior surface and direction was downward. Nutrient artery is very important for blood supply of long bones. Therefore, it is very important for surgeons to have sound knowledge of precise morphology and morphometric of nutrient foramen which will help in preserving vasculature of bone during various surgical procedures like bone grafting, the knee replacement, external and internal fixation of fractures and bone resection for tumors.

ABSTRACT

Background: The study was aimed at determining the variations of lateral epicondyle, capitulum and lateral trochlear crest of humerus and finding out the prevelance of different forms.

Materials and Methods: 60 dried Human humeri were examined grossly from the collection of Anatomy department, Pacific Medical College & Hospital for the location of lateral epicondyle, extent and shape of distal margin of capitulum and for the lateral trochlear crest.

Results: In 76.67% of humeri, lateral epicondyle was located at the same level/ slightly below the level of capitulum whereas in 23.33% of humeri, it was located above the level of capitulum, Distal margin of capitulum was Flat and extending onto distal surface in 83.33% of humeri where as it was Convex and extending onto posterior surface in 16.67% of humeri. Lateral trochlear crest was pooriy developed in 10%, moderately developed in 85% and well developed prominent in 5% of humeri.

Conclusion: This study may help in repairing the fractures/reconstruction of trochlea and capitulum, designing of elbow prosthesis, repairing the damage to radial collateral ligament as well as lateral epicondyle surgeries of humerus.

KEY WORDS: Lateral epicondyle, Trochlea, Capitulum, Distal end of Humerus.

INTRODUCTION

Humerus is the largest and longest bone in the upper limb, has expanded ends and a shaft. The lateral epicondyle occupies, lateral part of non articular portion of condyle. The capitulum is a rounded convex projection, considerably less than half a sphere which covers the anterior and inferior surfaces of the lateral part of the condyle of the humerus but does not extend onto its posterior surface. Trochlea is a pulley shaped structure that covers the anterior, inferior and posterior surfsces of the condyle of humerus medially and on its lateral side, it is

separated from capitulum by a faint groove [1].

Uptill now, distal end of the humerus was used by researchers for the studies like determination of Total length of humerus from the fragments of distal end of humerus, gender determination, forensic sciences and supratrochlear foramen studies [2-4]. These studies used complex statistics and measurements which were time consuming, so this study was conducted to determine different types of presentations of lateral epicondyle, capitulum and lateral edge of trochlea as well as their prevalence in dry human humerus by gross examination.

Knowledge of the these anatomical variations at the lower end of humerus is required to orthopaedic surgeons in repairing the fractures/ reconstruction of trochlea and capitulum, designing of elbow prosthesis, repairing the damage to radial collateral ligament as well as lateral epicondyle surgeries of humerus.

MATERIALS AND METHODS

This study was undertaken at Pacific Medical College and Hospital, Udaipur. A Total of 60 dry humeri were examined irrespective of their side and sex from the collection of Department of Anatomy, Pacific Medical College and Hospital, Udaipur. Distal end was examined for the following parameters:

1. Location of lateral epicondyle.
2. Shape and extent of distal margin of capitulum.
3. Lateral trochlear crest.

Fig. 1: (a) Lateral epicondyle at the same level of capitulum, (b) Lateral epicondyle above the level of capitulum.

Fig 2: (a) Distal margin of capitulum flat and extending on to distal surface of lower end of humerus, (b) Distal margin of capitulum convex and extends on to posterior surface of lower end of humerus.

Fig. 3: Lateral trochlear crest (a)poorly developed, (b)well developed and prominent, (c)moderately developed.

RESULTS AND DISCUSSION

In our study, Lateral epicondyle of humerus was found at the same level of capitulum/slightly below the level of capitulum in about 76.67% of humeri where as in 23.33%, it was well developed and located above the level of capitulum which may prove advantageous for added lever action of long extensors of fingers and wrist. High placed lateral epicondyle makes the trochlea easily accessible during the Built-on surgical techniques for distal humerus shear fractures [5]. As the Radial collateral ligament is attached to distal surface of lateral epicondyle [6], knowledge of exact location of lateral epicondyle is important to diagnose Radial collateral ligament abnormalities [7]. Among the varieties of capitulum, capitula with flat distal margin extending onto distal surface were 83.33% whereas capitula with convex distal margin extending onto posterior surface were 16.67%. Flat distal margin extending onto distal surface only may prevent the hyper extension of elbow. These variations may help in designing elbow prosthesis and capitular reconstruction. Lateral trochlear crest was poorly

developed in 10%, moderately developed in 85% and well developed prominent in 5% of humeri. Any fracture of trochlea involving the lateral trochlear crest makes the person susceptible for the capitular fracture as well [8]. So the knowledge of variations of lateral trochlear crest may help in diagnosis of extent of fracture and thereby guiding the surgical procedure. Presentations of various types and their prevalence are illustrated in the Table-1.

Table 1: Presentations of various types and their prevalence.

PARAMETER	VARIATIONS		
Location of lateral epicondyle (60)	At same level/ slightly below the level of capitulum(46) – 76.67%	Above the capitulum(14)- 23.33%	
Distal margin of capitulum (60)	Flat and extending onto distal surface(50) – 83.33%	Convex and extending onto posterior surface(10) – 16.67%	
Lateral trochlear crest (60)	Poorly developed (6) – 10%	Moderately developed(51) – 85%	Well developed and prominent (3) – 5%

CONCLUSION

Lateral epicondyle, capitulum and lateral trochlear crest do exhibit variations. Such variations of distal humerus have been studied least in india so far.Knowledge of these variations having variety of clinical implications such as in making elbow prosthesis, to diagnose extent of fracture and to determine mode of surgeries etc.

ABSTRACT

Fetal improvement is the fundamental part of maternal supplement stores & compelling transportation through the placenta. Consequently, any distinction in the placenta brings about inconsistent fetal advancement results of expanded danger of delayed sicknesses in the neonatal. This investigation was expected to find the impact of placental morphometry on infant anthropometry.

Materials and Methods: In current study lacentae were obtained from Obstetrics and Gynecology Unit & pacific medical college & hospital Udaipur and study was conducted in the Dept. of Anatomy, Geetanjali M.C. and Hospital, Udaipur (Rajasthan) from August 2018 to November 2019, by using standard operating methods in a pre-designed & pre-tested format, distributions of placental morphology & newborn anthropometry are stated in percentage & box plots, evaluation of variance is used to study the differences in means of placental morphometry in various groups of newborn anthropometry.

Results: The Means & SD of placental morphometry; weight, volume, surface area & thickness were found to be 440 ± 100gm, 386 ± 101 ml, 230 ± 50 cm sq, & 2.1±0.4cm respectively, whereas Mean for birth weight & length found to be 2700±500 gm & 46.6 ±2.5cm of newborn. Placental morphometry & newborn anthropometry improved significantly with pregnancy.

Conclusions: The study extrapolates that maternal pre-pregnancy & during pregnancy condition status along with placental morphology determines neonatal health status. Hence, variations in the maternal nutrient status lead to an adverse gestational outcome.

1. Introduction

Placental advancement was perceived from fossil indication of Ichthyosaurus, in excess of 170 million years prior. Circle molded haemochorial placenta of various humans, happened all through the Eutherian ancestry.[1]

Chorionic plate resultant from the developing incipient organism & decidual plate resultant from a change of the uterine covering of the mother, Consequently, the human placenta develops from both uterus & creating embryo.[2–5] In beginning the placenta assesses the embryo in size & keeps on creating till term. As gestation propels, it grows moderately more modest & by term, the proportion of its weight to that of the baby is about 1:6 to 1:72.

The chorionic plate part expresses the placental surface part covering the uterus & depicts, the number of maternal winding courses & veins are plausible gives to surface area.[6] Placental turn of events & profitability are the main fetal wellspring of supplements & oxygen flexibly. Placental improvement is around achieved by beginning third trimester, while the thickness of placenta increments in last third trimester.[7–10]

Placental thickness, by distinction, denotes the measure of arborisation of the villous slender bed, the genuine locus of maternal-fetal trade.[11] Placental volume was clearly comparative with the birth weight of the baby.[12]

Unordinary chorionic plate shape regularly uncovers pathologic villous decay from the finish of the principal

https://doi.org/10.18231/j.ijcap.2020.077

trimester or placental infarct. Subsequently, these boundaries of placental advancement might be crucial pointers of placental load at delivery.[13]

2. Materials and Methods

The current examination was coordinated in the Department of Anatomy, Geetanjali Medical College and Hospital, Udaipur (Rajasthan) and pacific clinical school and emergency clinic Udaipur. Placentae were assembled from Obstetrics and Gynecology Unit. Data was gathered from August 2018 to November 2019. The examination was directed to 391 mothers & their singleton posterity. Information about mothers & consent was taken starting the real examination. Subjects without antenatal enrollment during the principal trimester & with history of pre-pregnancy key & industrious ailments were banished. Placental morphometry & baby limits were noted on the predesigned & pretested design.

1. Techniques for example assortment, planning, & evaluation of placental morphometry:[14]
   a. Placentae were assembled not long subsequent to secluding the newborn from the umbilical rope, assembled placentae were assessed inside & out washed under the running water, starting there, layers were overseen.
   b. The models were marked with numbers for ID & were delivered to the capacity lab by setting in a 10% formalin compartment.
   c. The weight of each placenta of newborn was kept constrained by the automated measuring scale CS-8316(CE guaranteed) & recorded with an exactness of 1 gm.
   d. The maternal surface locale of the placenta was resolved using the formula.[15]
2. Boundaries of infant evaluated were:
   a. Gestational age, weight & height of the newborn.
   b. The G.A. was recorded from LMP & further insisted by USG as 28-34, 35-36, 37+ wk.
3. Birth weight calculated using Digital baby measuring scale CS-8316 (CE asserted) with an accuracy of 10 gm.

2.1. Statistical analysis

Statistical Analysis was carried out using Analysis of Variances and comparisons of means were studied by t-test was done utilizing SPSS-16, the Box plots were set up to examine the relative circulations placental morphometry & infant anthropometry.

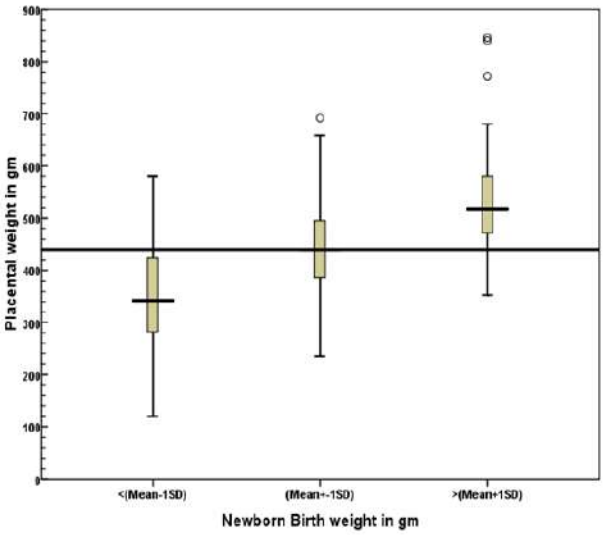

Fig. 1: Placental weight by birth weight

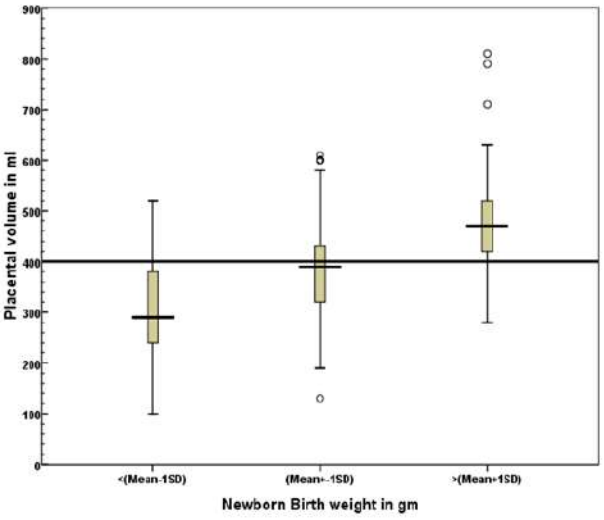

Fig. 2: Placental volume by birth weight

3. Result and Discussion

Mean birth weight if there should be an event of the current assessment was 2,700 gm, lesser than all recently referenced considers, yet practically like Mysore Parthenon study as they were from similar neighborhood belt of India.[16–18] Placental development is related with pregnancy results, as the placental morphology & its physiology decide the development direction of the embryo. Mean birth weight in the current assessment was nearer to that of Indian newborn children, it is decided the ideal extent of birth weight in made countries as 3000-4000 gm to keep up a key good ways from maternal & fetal mortality & morbidity[19] referred to the mean & SD of birth weight

of Malays, Chinese, & Indian youngsters as 3126±300gm, 3245±300gm & 2935±400gm respectively.[20]

In the current assessment birth weight indicated a dependably sure & tremendous connection with the going with limits: The current assessment declares the placental weight, volume, & surface domain are basic determinants of birth weight.[21] Placental morphometry: Weight ($p<0.001$), volume ($p<0.001$), surface zone ($p<0.001$), thickness ($p<0.05$), baby Length ($p<0.001$), current examination showed 28.2% LBW kids described as under 2500 gm.

LBW was identified with an extended risk of perinatal mortality & those youngsters who suffer are slanted to have hindered immune limit, diminished muscle quality, & bear cardiovascular diseases[22] so, birth weight can be used as a strong marker of newborn child unsullied perseverance.

A Norway based study declared the mean newborn child length of 50.8±SD 2.320cm. The placental weight mirrors the turn of events and capacity of the placenta and is corresponded with gestational age. The current examination indicated that placental weight expanded by birth weight and gestational age, which agrees with past perception. Another Indian assessment itemized the mean newborn child length of 47.06±1.18cm. The mean baby length from Malays 48.8 cm, Chinese 49.5 cm & Indians 48.1 cm, & assumed that Indian youngsters were more restricted than Malays & Chinese neonates.[23] The mean length 48.7 cm of newborn child & uncovered an immense positive association between's the placental weight & baby length.[24]

4. Conclusion

Maternal pre-pregnancy weight mean (48.4±8.9 kg) with 14.1% of women weighing less than 40 kg. Percentiles of birth weight & placental morphometry: weight, volume, & surface area with maternal pre-pregnancy

weight (p<0.001) & surface zone (p<0.05). Gestational weight gain was basically identified with birth weight (p<0.01) regardless, placental morphometry. Maternal height followed dissemination where 08.2% of pregnant women had height under 145 cm & 59.8% were from height pack 150-159 cm. The mean maternal height was 153.9±6.7cm. Percentiles of birth weight growing example with maternal height yet placental morphometry & Birth weight (p<0.05) extended dependably with the growing maternal height, nevertheless, placental morphometry didn't

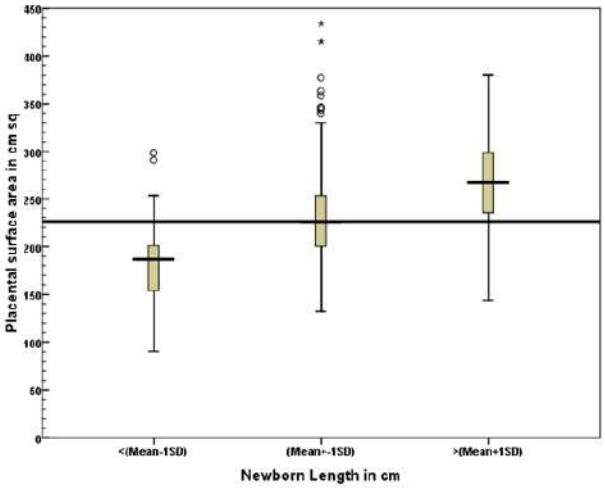

Fig. 7: Placental surface area by newborn length

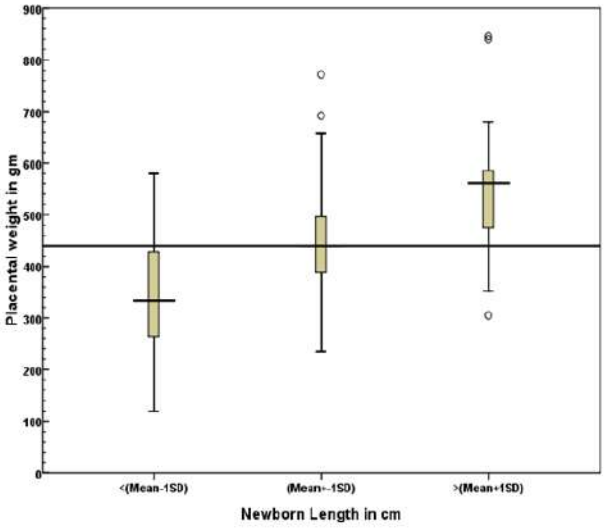

Fig. 5: Placental weight by newborn length

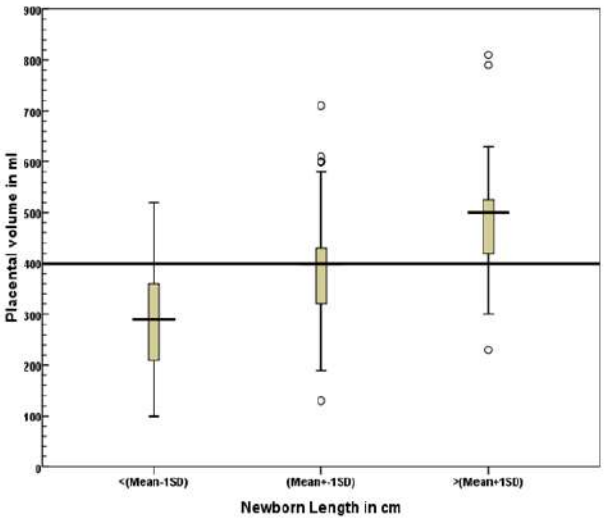

Fig. 6: Placental volume by newborn length

show any consistent association

5. Limitations

Placental morphometry determines the birth weight & newborn length. However, the results need further validation in other setups with a large number of subjects.

6. Source of Funding

None.

7. Conflict of Interest

The authors declare no conflict of interest.

ABSTRACT

Background: Nowadays study of dermatoglyphics has an extraordinary significance in legal and criminal explores. Additionally, its investigation is identified with some hereditary sicknesses has an enormous application. Diabetes Mellitus is the silent killer of humanity and general medical issue. Dermatoglyphics might be viably utilized as a screening methodology in future and may help in the early recognition of instances of diabetes mellitus.

Materials and Methods: In our study, total of 100 patients were selected from the out door patient department from the hospital, out 0f 100 patients 50 patients those are suffering from diabetes made the experimental group and the other those are having no systemic condition made the other group or the control group. The establishment of the connection between the two groups by examining the each group the fact of presence or absence of dermatoglyphic design. In this total finger ridge count, indian ink technique was usd for taking up the hand, along with total ridge count of finger, absolute finger ridge count, ridge count for distal as well as lateral deviation along with palmer frequency design computerised along with lateral deviation with design frequency of the c- line and angles, which represent the qualitative boundary.

Results: The result that has been obtained from our study reveals that the total finger count of the ridge along with ridge count of the finer absolute, along with a-b count of the ridge were found to be higher in all the groups of the patient but found to be insignificant statistically. Angle "atd" that is present over both the sides of the hand in the patient were found to be expanded in all the groups that involve both the experimental groups and the control group, but with an exception in males that too in left side, but still they differ on the right side that too significantly ($p<0.01$, overall) and on the left side i.e. in case of females with $p<0.001$. The angles of tad and as well as 'tda' which were present over the two sides of the with respect to all the groups, that include the experimental one and the control one, but with an exception with respect to males with left 'tda' and in other case they significantly differ in case of females with left tad with $p<0.01$ and in case of right side tda with $p<0.001$ and with respect to all the groups with reference to right 'tda' with value of $p<.01$ the arch advanced frequencies along with the circle and the whorl in case of females with respect to the over all groups with an exception with loop were found to be increased significantly with p value i.e. $p<0.05$. The design of the spiral along with remnant were found to be totally limited to the thenar along with the hypothenar region in the male patients when get contrasted with the controls.

Conclusion: By the results of our study we concluded that, there is expansion in the radial variety and absence was found in case of proximal variety and the designs of the c – line in case of diabetics were reduced when it is compared to the control group. Our study results demonstrated that dermatoglyphic abnormalities can be utilized as a device which act as analytic for predicting the chance for the development of the disease known as diabetes in future.

1. Introduction

Dermatoglyphics deals the logical investigation of epidermal ridge designs on the palmar and plantar part of fingertips, palms, soles and toes.[1] The term 'Dermatoglyphics was coined by Cummins and Midlo (1926) and was derived from the Greek words 'derma' signifies skin and 'glyphics' signifies carvings (Penrose LS, 1963).[2,3] The skin on the palmar and plantar surfaces of man not smooth. It is scored by inquisitive ridges, which form a variety of designs as the dermal ridges start developing during the third intrauterine week as a result of physical or topological power.[3] Dermal ridges along with the arrangements which are once framed are not influenced by the age, advancement and ecological changes in the postnatal life thus it can possibly anticipate different hereditary and obtained disorders with a hereditary impact.[4]

Broad clinical interest in epidermal ridges grew distinctly over the most recent couple of years when it became apparent that numerous patients with chromosomal variations had strange ridge design. Assessment of skin ridges, subsequently vowed to give a basic, reasonable methods for data to decide if a given patient could have a specific chromosomal deformity.

1.1. Dermatoglyphics offers at least two significant focal points.[5]

1. The epidermal ridge designs on the hand and sole are completely evolved at birth and so, stay unaltered forever.
2. Scanning of the ridge patterns or recording these perpetual impressions can be cultivated quickly, reasonably and with no injury to the patient.
3. Finally, the relevance of dermatoglyphics is not to diagnose, but it is preventive by predicting a disease. Similarly, it is not for defining an existing disease, but for identifications of people with the genetic predisposition to develop certain diseases.

Diabetes Mellitus is the silent killer of mankind and general medical issue. Accordingly, researchers are searching for new techniques for its initial diagnosis and management. Indeed, even before that the primary expectation of it might assist with taking some prophylactic measures. One of the aetiology of Diabetes Mellitus is genetic. In this investigation, we are attempting to indicate the dermatoglyphic attributes to see if some particular quality exists in the Diabetes Mellitus patients.

2. Materials and Methods

Total number of patients included in the study is 60 and all these 60 patients were contrasted and 60 patients were taken as control group. Confirmation that the patient is having diabetes mellitus id totally depend upon the clinical signs and symptoms given by the patient along with there blood glucose levels.

2.1. The Indian Ink method (Cumins and Midlow, 1961)

The technique that was introduced by cumins and midlow in the year 1961 that is now known as indian ink technique was utilized totally in the process of impression making with the help of camel copying ink.

The material that is utilised in our study is a piece of glass plate with dimension of 8.5x11 inches along with two plain paper of dimension 8.5x11 inches, a bottle of dimension10x4 inches, roller which is used for the dispersion of the ink, table, scale, pointed HB lead pencil along with mercury light, pointer for marking and a protractor, chemicals for washing the hand like ether and a good quality of central focal point which is enhancing.

The hands should be washed thoroughly with the help of chemicals and water and chemical ether was used to clean the dampness. Very small amount of replicating ink crushed out from the roller on a thin film for the process of direct ink over the fingers. The palm was spreaded with the help of roller that is inked to cover the palm, that has to be printed for appraisal. The paper was engaged over the compartment that is in round shape and the fingers were open after than the palm should move by the application of force over them and in the mean time by permitting the paper along with container to move in forward direction [Figure 1]. The fingerprints that were taken by different turns of the fingers both in inking and priting to get the proper impression of the finger prints. This technique will help us in recording the complete impression of the palm. After than all these prints were concentrated by central focal point that is intensifying for all the observed observations with respect to and under different heads.

3. Obeservations and Results

All the findings were recorded in a careful manner to get the quantitative as well as qualitative highlights of the dermatoglyphic from the prints from different hand of the different patients, that constitutes total of 60 patients, out of 60 30 were male and 30 were female and total number of patient under control group is 60, which constitutes of 17 females and 43 males.

45 percent was the total whole finger ridge count of the different patient examined with a range of 150-200 and for the control group it was concluded as 43 percent with a range of 100 to 150 for the control group. Mean for the diabetic group is 143.12 and for the control group it was

134.23, which is found to be not differ significantly along with the above said comparative difference was additionally not significant in Table 1.

It was revealed that 43 percent was the absolute finger ridge count for the diabetic group with a range of 100 to 200 and the same is 45 percent for the control group with a range of 200 to 300. The difference which was found for their mean value is 211.48 for the experimental group i.e. the diabetic patient group and 196.43 for the other group i.e. the control group.

The point mean values of the patient with 'atd' of the right was revealed to be 43.92 and the same for the control group was revealed to be 39.41 and these two values were fond to be differed significantly with p<0.01. While we went for correlation regarding with sex wise, in case of females the mean values for left angle was found to be 41.68 in case of the experimental group i.e. the diabeteic group and 38.96 for the control group and a significant difference was found with p<0.001. on the other hand the angle distribution for the right side was in the range under 60 to 69 which constitutes about 46 percent when get contrasted with the other group thai is the control group. On the left side this was inverted on correlation with angle 'tda', both the groups i.e. experimental and control group revealed significant difference with p<0.01 over the right side. Distribution range on the right side was revealed to be 70-79 which is found to be 48% in case of experimental group i.e. diabeteic patient group, when get contrasted with 80-89 which constitutes about 66 percent in the other group

P-Value Significance of Digital Pattern Frequency of Finger Tip Pattern Distribution

i.e. the control group.

The highest didtribution pattern for whorl, loop and the arch was found in the second, fourth and the fifth finger, although along with above said they were available with respect to fourth, fifth and third finger in the other group too, i.e. in the control group. 41% patients were found in case of experimental group and 52% was found in case of control group with respect to whorl spiral and in case of symmetrical whorl 41% constitutes for the experimental group and 57% for the control group present more towards with respect to fourth finger along with it loop whorl with two fold was revealed to be present with respect to first finger in case of experimental group which constitutes about 23% and 16% for the control group and in case of fifth finger for loop ulnar was found to be 80% for the experimental group and 76% for the control group, along with it loop radial was present more in case of second finger for experimental group for 8% and 7% for the control group. This contrast between the two groups i.e. for experimental as well as control group were revealed to be statistically significant.

In case of the experimental group i.e. for diabetic patient the rate of recurrence for whorl, arches and the loop were found to be 47.2%, 5.2% and 48% and with respect to contrast with the control group, in which it was found to be 37.6%, 4.35% and 57.7% respectively and individually. These difference among the different variables was found to be significant with $p < 0.05$, on the other hand these all were found to be insignificant when all the fingers were compared individually as single different entity and shown in Table 6.

2% of remnant design was revealed to be present in the thenar area in the experimental group patient only. The design of two loop was found to be present in the I4 region in both the groups i.e. the experimental group and the control group ie. For the experimental group it was found to be 8% and for the control group it was found to be 2%. In the I3 area loop design was mostly found in 53 percent cases of the experimental group and in the I4 area which constitutes about 50%.

It was noticed that c – line was not present in case of ulnar, radial and proximal varities. It was noticed that the design of c line proximal is found not to be present in case

of diabetic group i.e. the experimental group, on the other hand it was found to be significant in the other group i.e. the control group on the left side and constitute about only 10 percent. On the left side it was found that the c line was missing in the control group 12% as shown in fig.3, while it was seen to be available on both the sides in the control group i.e. on right side in 6% cases and on the left side in 14% of the cases. And in diabetic patients it is found that more radial tendency pattern was present as compared to the control group, but when seen in the ulnar group the ulnar tendency finding found to be turned

4. Discussion

The greek meaning of the word, dermatoglyphics is derma, which further means glyphae and skin, glyphae means cutting. Dermatoglyphics is verymuch remarkable field, which has the tendency and totally gets influenced by different genetic varities, as found in syndactyly, down's condition. Diabetes is in the other words is multifactorial illness which has it hereditary tendency. Hereditary features of dermatoglyphic acclimates to the framework of polygenic.[6]

In this current examination it is revealed that total finger ridge count was found to be more in case of the diabetic patient i.e. the experimental group when compared to the control group, another study done by Julian L et al reveals the same.[7] And the mean absolute finger ridge count is found to be more in male patients and less in case of female patient, our result is in relevance of the result given by Vera M et al.[8]

a-b number of ridge inclined was found to be not significant in case of the experimental group patient, our study this result is in favour of the result given by Ojha P et al.[9] which reveals that p<0.001 in their study. In case of the diabetic patient it was found that, there is rising of whorls along with arches and a reduction with respect to loops was not significant. The results of our study was found to be unsurprising with the consequences of Li Yanhua and Zia et al, they revealed increase in number of whorls along with arches along with lower in loop number in the selected patients.[10,11] It is found that the recurrence of the palmar design in case of both the groups is found to be insignificant statistically, that was in favour of the result given by Dam PK et al[12] our study revealed that there is decrease in pattern of recurrence in the I4 zone in case of male patient that are having diabetes, this observation was in favour of the results given by Zeigler et al[13] the design of c line looked for ulnar, proximal, radial classes. All of the above said three combinations tha are barring from the radial one was found and revealed to be lesser in the group of patients, those shows relevance with the results of examination of the study being conducted by Pathan FKJ et al.[14] It was found that on both the sides in case of diabetic patient the proximal variety was found to be not present on the other hand in case of the second group i.e. the control group it is present on the left side only.[15]

It was found that on the both sides in case of male and female patients 'atd' purposes of the patients were found to be more in or present study and it was found to have relevance with the results of Barta et al.[16] The angle 'tad' on the best right side fall under the range of 60 to 69 which constitutes about 46 percent out of all the cases in the diabetic patient, but in case of the second group i.e. the control group they fall in range of 50 to 59 i.e.46 percent on the left side. In case of diabetic females left 'tad' points was found to be significantly differentiated i.e. p>0.01 as compared to he normal or healthy females.

'tda' angle among the compared groups on the right side present with a contrast that is significant i.e.p<0.01 on the other hand bet the male as well as the female group, distinction present on the left side revealed to be insignificant in all the groups. So both the angle i.e. 'tda' and 'tad' that seen in current study were not examined by some other researcher. The findings of this investigation might be normally twisted by the dermatoglyphic irregularities which were related with ordinary people who were inclined to develop diabetes sometime in future.

5. Conclusion

The dermatoglyphic highlights of the current study might be utilized as an interesting diagnostic instrument to make a temporary conclusion and to distinguish the people who are in risk, yet it needs more broad investigations in an enormous number of patients.

6. Conflicts of Interest

All contributing authors declare no conflicts of interest.

7. Source of Funding

ABSTRACT

Aim: To study variations in external morphology of cadaveric gall bladder. Materials and

Methods: This study was undertaken on 30 cadaveric liver and gall bladder specimens in the Department of Anatomy at Tertiary Medical College of West Uttar Pradesh in terms of maximum length, maximum transverse diameter, thickness, shape, external variations and length of gall bladder below the inferior border of the liver using vernier caliper.

Results: Gall bladder had length ranging between 5.52 and 11.32 cm, transverse diameter between 2.78 and 5.57 cm, thickness at neck, body and fundus was not found uniform. The commonest shape observed in this study was pear shaped. The length of gall bladder below the inferior border of liver varied between 0.46 and 3.93 cm.

Conclusion: Since the incidence of gall bladder illness in our country is increasing day by day hence morphological knowledge is essential, not only from the point of biliary disease but also with respect to the various laprascopic, surgical and invasive techniques for example T-tube cholangiogram in the proper diagnosis and management of gall bladder and extrahepatic bile duct diseases. The morphological data may be useful to the surgeon's radiologists and anatomists.

Key words: Gall bladder, Morphometry

1 INTRODUCTION:

The gallbladder is a slate-blue, piriform sac, partly sunk in a fossa in the right hepatic lobe's inferior surface. It extends forward from a point near the right end of the porta hepatis to the inferior hepatic border. Its upper surface is attached to the liver by connective tissue; elsewhere it is completely covered by peritoneum continued from the hepatic surface. It is a blind ending diverticulum attached to the common bile duct by the cystic duct [1].

Gall bladder is 7–10 cm long, 3 cm broad at its widest and 30–50 ml in capacity[[1]. It is described as fundus, body and neck. The fundus is the expanded end which projects down, forward and to the right, extending beyond the inferior border of the liver to come in contact with the anterior abdominal wall behind the ninth right costal cartilage. The body is directed up, back and to the left; near the right end of the porta it is continuous with the gallbladder neck. The neck is narrow projecting forwards and then abruptly back and downwards, to become the cystic duct.

Though human beings are thought to be similar in their general anatomical phenotype, but when we come to investigate one particular region with more detail, it is surprising how frequently we meet one sort or another type of variations [2]. Understanding of these variants is important before laparoscopic procedures.

The present study will be of great help to surgeons and radiologists to understand the external morphology of the gall bladder.

2 MATERIALS AND METHODS:

This study was carried on 30 liver and gallbladder specimens obtained from 10% formalin fixed cadavers in the Department of Anatomy of Shri Ram Murti Smarak – Institute of Medical Sciences, Bareilly, Uttar Pradesh.

Cadavers with obvious abdominal surgery and crush injury to the abdominal organs were excluded from the study.

The parameters studied were the maximum length, maximum transverse diameter, thickness, shape, external variations of gall bladder, Level i.e. length of gall bladder below the inferior border of the liver.

The maximum length was measured from the porta hepatis to the mid-point of the fundusFigures 1 and 2 and the maximum transverse diameter Figures 3 and 4 was measured from the porta hepatisFigure 5 as well as from the

inferior border of the liver Figure 6 by using vernier caliper in centimeters.

The shape and any variation in external appearance of gall bladder were noted. Part of the gall bladder i.e. fundus that lie below the inferior border of liver was noted.

The thickness of the gallbladder wall was measured by fine dissecting method. A longitudinal incision was made by sharp B-P blade through the peritoneal smooth surface of the gallbladder from fundus to neck and interior of the gallbladder was cleaned with jets of tap water. Then the thickness of wall of the gallbladder was measured in centimeters at the maximum transverse diameter of the fundus, body & neck region of the gallbladder with the help of vernier caliperFigures 7, 8 and 9. For taking measurements the non peritoneal surface was not chosen due to rough and irregular surface.

3 RESULTS:

Maximum length of gall bladders Table 1:

Average length of gall bladder was found to be 8.25 cm. The smallest gall bladder was 5.52 cm in length and the largest had length 11.32 cm. 70 % (21/30) had length ranging between 7 and 10 cm.

Table 1. Length of gall bladders

Length in centimeters	No of specimens	Percentage (%)
< 7	6	20
7 – 10	21	70
> 10	3	10

Maximum transverse diameter of gall bladders Table 2:

Mean breadth of gall bladder was 4.30 cm. The shortest transverse diameter was 3.06 cm and largest 5.57 cm. 53.33% (16/30) had a maximum transverse diameter between 3 and 4 cm.

The distance of the maximum transverse diameter of gall bladder from the porta hepatis was found to be ranging between 2.46 and 7.06 cmFigure 5 and from the inferior border of the liver between 1.43 and 5.37 cm Figure 6.

Table 2. Transverse diameter of gall bladders

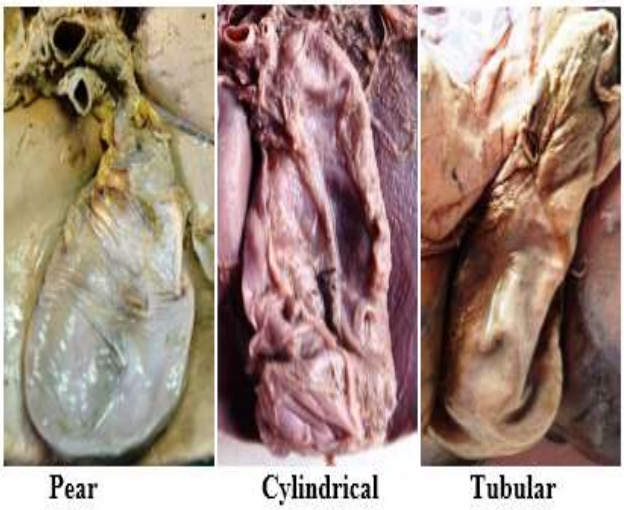
Transverse diameter in centimeters	No of specimens	Percentage (%)
< 3	1	3.33
3 – 4	16	53.33
> 4	13	43.33

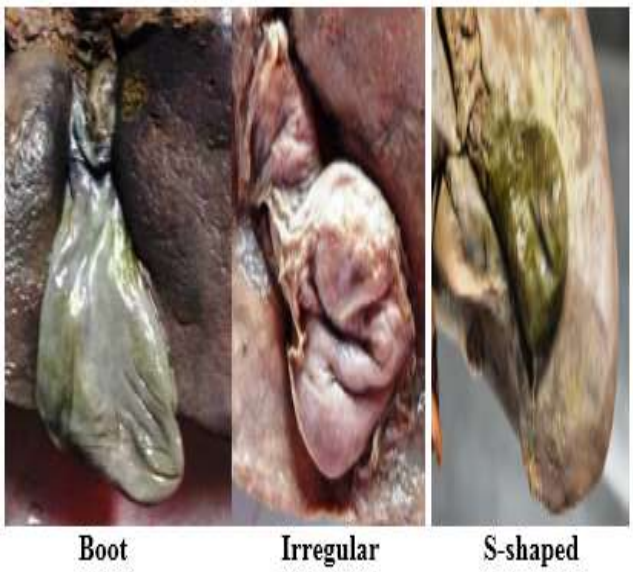
Shape of gall bladder:

The gall bladders were classified according to their shapes. Various shapes were observed. The commonest shape found was pear shaped (21/30, 70%). Their incidences are shown in theTable 3.

Table 3. Different shapes of gall bladders

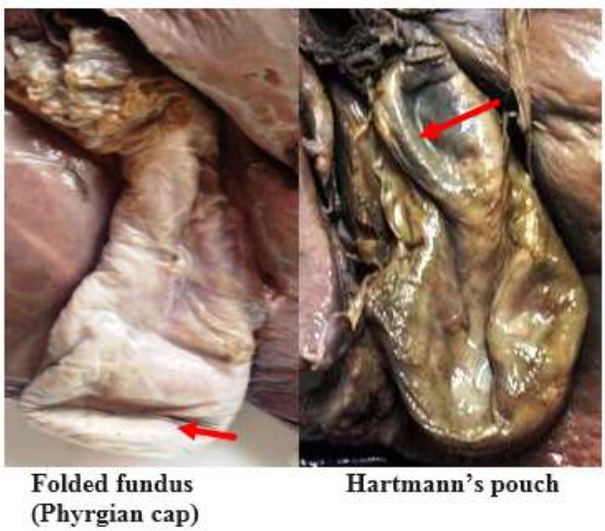
Shape	No of specimens	Percentage (%)
Pear shaped	21	70
Cylindrical	3	10
Tubular	2	6.66
Boot	1	3.33
Irregular	1	3.33
Retort	1	3.33
S-shaped	1	3.33





External appearance of gall bladder:

Foldings of neck and fundus (whether anteriorly or posteriorly) were observed. Folding of fundus was noted in 2 out of 30 specimens of GB. Hartmann's pouch was also observed in 1 specimen.



Length of gall bladder below inferior border of the liver:

21 gall bladders were crossing the inferior border of the liver and the length varied between 0.46 – 3.93cm Figure 10.

Thickness of gall bladder:

The thickness of gall bladder was found different at neck, body and fundus.

Figure 10.

Table 4. Thickness of gall bladders

	Thickness (mm)
Fundus	1.35 – 1.69
Body	1.30 – 1.75
Neck	0.46 – 0.95

4 DISCUSSION:

The gall bladder, liver and the biliary ductal system develop from the hepatic endodermal diverticulum of the foregut, at the beginning of the fourth week of development .This diverticulum rapidly proliferates into the septum transversum and divides into two parts – the cranial part develops the liver and the bile ducts while the caudal part gives rise to the gall bladder and the cystic duct. Any arrest or deviation from the normal embryological developmental process may result in some sort of malformation of the gallbladder and of the biliary system [3] .

Comparison of length and breadth with other studies has been shown inTable 5.

Table 5. Length and Transverse diameters of gall bladder as re-ported by other authors

6.	Present study	5.52 – 11.32cm	3.06 – 5.57cm

Size of gall bladder varies in different diseased conditions as well as in some physiological conditions too. It may be impossible sometimes to distinguish between various parts described. The size of gall bladder may increase after vagotomy, diabetes, pregnancy, sickle cell disease, after cystic duct or common bile duct obstruction [6].

Shapes of gall bladder vary and various authors have described various shapes as seen inTable 6. We found pear shaped gall bladder as most common (70%).

8.	Present study	Pear (70%), Cylindrical (10%), Tubular (6.66%), Boot, Irregular, Retort and S – shaped (3.33%)

The gall bladder is relatively constant in its development and the two most significant variations are the folded fundus and variation at the neck of the gall bladder [6]. The folded fundus of the gall bladder, also called as the Phrygian cap, was reported in 3 – 7.5% of gall bladder by Lichtenstein M & Nicosia AJ [9].They proposed that it could due to a disproportion between the size of the gall bladder and that of the gallbladder bed, but without any pathological significance. Deutsch AA et al [10] and Gore RM et al [11] recorded folded fundus in very few percentage of gall bladder. Meilstrup JW et al [12] observed that gross bending of the gallbladder could occur posteriorly or anteriorly and lead to bizarre or unusual shapes when visualized by sonography and other imaging techniques. Futara G et al [13] observed that there was a significantly higher prevalence of kinking of the gallbladder and Hartmann's pouch in the females than in male subjects which could be related to the higher rate of gallstone formation and biliary tract diseases in females. In our study, we found folded fundus in 2 specimens (6.66%).

The length of gall bladder below the inferior border of the liver in our study was between 0. 46 – 3.93 cm. Prakash AV et al [7] reported between 0.4 – 2.5cm.This is the most susceptible part of gall bladder that can be damaged in laparoscopic procedures [1].

The thickness of the gall bladder at fundus, body and neck were 1.35-1.69mm, 1.30 – 1.75mm and 0.46 – 0.95mm

respectively. We couldn't find any literature regarding this parameter. Gallbladder diseases are diagnosed clinically and confirmed by various non invasive as well as invasive procedures and wall thickness is the most important indicator to diagnose such diseases [14]. In diseases such as cholecystitis, carcinoma and metastasis of gall bladder.

However congenital anomalies of gallbladder are rare and can be accompanied with other biliary and vascular malformations [15]. Due to these anatomical variations, complications seen were bleeding and biliary leaks leading morbidity [16]. The comparative study involving GB morphometry in cadavers and sonographic/ radiological findings should be undertaken.

5 CONCLUSION:

The occurrence of bizarre forms of anatomical variations of gall bladder and extra-hepatic biliary tree though are not common but can be of clinical importance, however comprehensive study of the morphological variations of the gall bladder and their incidence is relatively scarce. Most of the interventional procedures in this modern era are done laparoscopically and there is tremendous increase in number of laparoscopic cholecystectomies. So, thorough knowledge of possible variations in morphology of gall bladder is important. Awareness of these anomalies will decrease morbidity, and re-exploration in these patients. This article will be of utmost useful to the surgeons and radiologists to understand and identify possible variations of GB morphology.

ABSTRACT

Aim: To study the variations in gross morphology and any change in histological architecture in cadaveric liver specimens and correlate with development in intrauterine life.
Materials and Methods: The livers were obtained from the cadavers during dissection and museum in the department of Anatomy, MCI recognized private medical college in North India. The morphological and histological observations were documented.
Results: Morphological variations were observed and classified. Histologically all specimens appeared to be normal.
Conclusion: The knowledge of such variations is important to anatomists, morphologists and embryologists for developmental anomalies. This will be beneficial for the surgeons for planning surgery involving liver and radiologists for interpretation of CT scans and MRI images.

1. Introduction

The liver is wedged-shaped, largest of the abdominal viscera, occupying most of the right hypochondrium and epigastrium, and frequently extends into the left hypochondrium as far as the left lateral line. As the body grows from infancy to adulthood, the liver rapidly increases in size. The size of the liver also varies according to sex, age and body size. The capsule is no longer thought to play an important part in maintaining the integrity of the shape of the liver.[1]

The liver is responsible for a wide range of metabolic activities including homeostasis, nutrition, immune defences, blood detoxification and purification, synthesis of plasma proteins, production of bile and the metabolism of carbohydrates, fats and proteins. In man, the liver is essential for survival since there is no artificial organ or equipment to compensate for the absence of liver function.[1] It is an important site of haemopoiesis in the fetus.[1]

The complexity of liver function and its importance in body homeostasis has encouraged many anatomists to study the morphological features of the organ in considerable details. Despite recent technological advances in the evaluation of liver parenchyma using imaging techniques, such as computed tomography or nuclear magnetic resonance,[2] detailed studies of the macroscopic anatomy of cadaveric livers can still contribute to the identification of important anatomical variations. In many cases, such variations have enabled researches to understand specific responses to therapies applied in the treatment of liver disease.

The major fissures are the important landmarks for interpreting the lobar anatomy and locating the liver lesions. In the era of imaging and minimally invasive approaches, it is very important on the part of both the radiologists and operating surgeons to have a thorough knowledge of the anatomy and the commonly occurring variations of this organ. Anatomists witness most of the variations of the lobes and fissures of the liver. Although the segmental anatomy of the liver has been extensively researched, there

https://doi.org/10.18231/j.ijcap.2020.021

are very few studies regarding the surface variations of the liver.

The aim of the present study was to investigate the type and frequency of anatomical variations and to find out any histological changes and correlate these with intrauterine development, in a collection of cadaveric livers.

2. Materials and Methods

Thirty nine (39) livers from adult human cadavers, fixed in 10% buffered formalin solution available in the department of Anatomy, MCI recognized private medical college in North India were studied. Age and gender of these specimens were not known. The specimens looked apparently normal. Histological sections from cornu and lingular process (if present) and different areas from the lobes in other specimens were taken and processed by H and E staining. These were observed for any variations in archi tecture and cellular structure.

3. Observations and Results

3.1. Morphological observations

Livers were examined on different occasions by two observers. The results obtained were compared and ratified. The distinct morphological characteristics observed were recorded on data sheets. On the basis of these descriptions, the organs were classified into ten groups (Table 1). The lingular process of left lobe (Type 8) was further defined according to shape (Table 2).

Table 1 shows different variants of liver. Type 1 is defined as the morphologically normal liver as classically described in the standard textbooks.[1,3], The present study showed an incidence of 28 specimens of type 1 (71.79%; Figure 1).

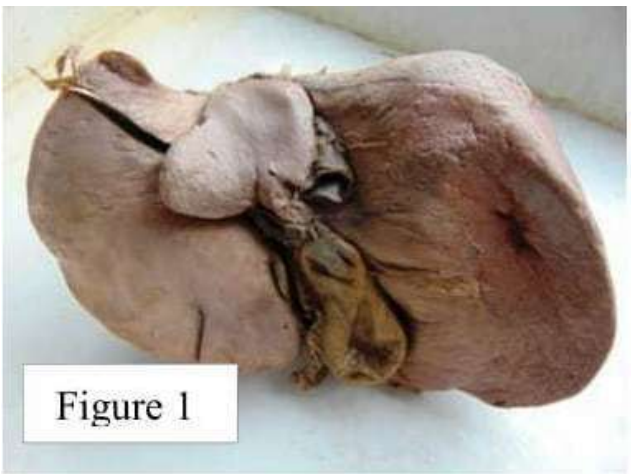

Fig. 1: Normal liver

Type 2 is liver with very small left lobe with incidence of 1 specimen (2.56%, Figure 2).

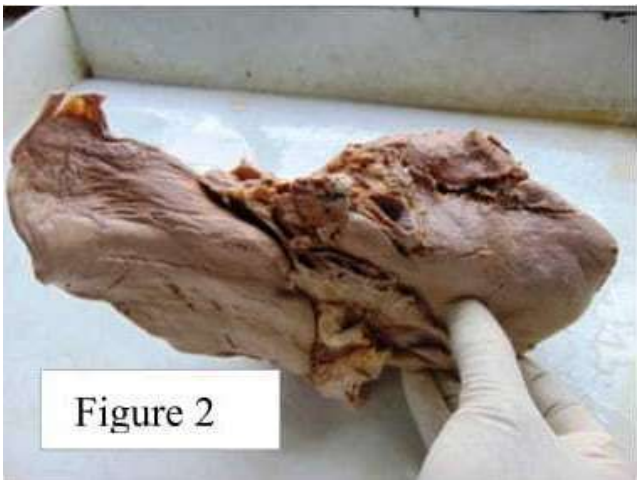

Fig. 2: Very small left lobe

Type 3 is defined as transverse "saddle-like" liver (1 specimen; 2.56%) as seen in Figure 3.

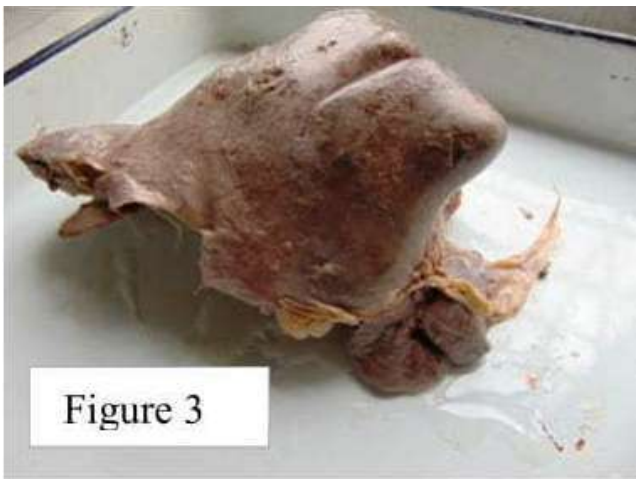

Fig. 3: Saddle-like liver

Types 4 (Figure 4), 5 (Figure 5) and 6 (Figure 6) are defined as livers with very deep renal impression, very deep costal impressions and diaphragmatic grooves respectively with incidence of 1 specimen each (2.56%).

Type 7 is defined as liver with enlarged left lobe (Figure 7). It was seen in 1 specimen (2.56%).

Type 8 is defined as liver with lingular process of left lobe (3 specimens; 7.69%). Lingular process is defined as tongue-like projection from the margin of liver.

Type 9 and 10 are defined as bicornuate (1 specimen; 2.56%, Figure 11) and unicornuate (1 specimen; 2.56%, Figure 12) left lobes of liver respectively. Cornu is defined as quadrilateral process projecting from the margin of the

Fig. 4: Very deep renal impressions

Fig. 5: Very deep costal impressions

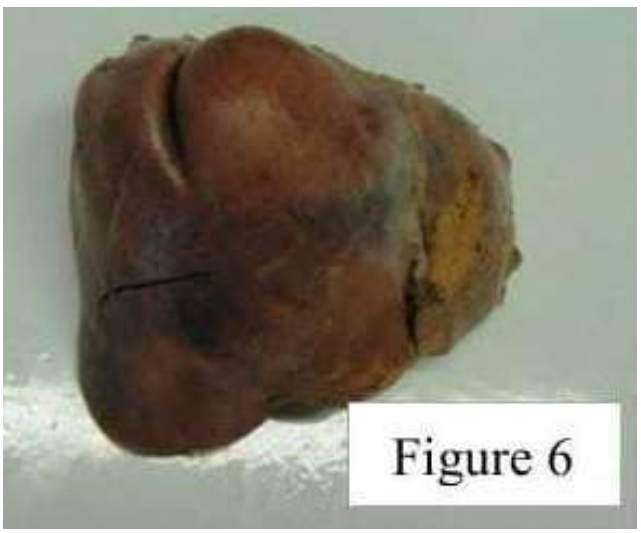

Fig. 6: Diaphragmatic grooves

liver.

Table 2 shows different shapes of lingular process of left lobe. They have been categorized into three types: apical (1 specimen, 2.56%; Figure 8), conical (1 specimen; 2.56%, Figure 9) and rounded (1 specimen; 2.56%, Figure 10).

Fig. 7: Enlarged left lobe

Fig. 8: Apical lingular process of left lobe

3.2. Histological observations

Sections for histological examination were taken from the cornu, lingula and different sites of the left and right lobes of all 39 specimens. All the histological sections taken from the liver specimens showed normal architecture. There was no change in cellular arrangement of cords and sinusoids were normal (Figures 13, 14, 15 and 16).

4. Discussion

Embryologically, the liver primodium appears in the middle of the 3^{rd} week as an outgrowth of the endodermal epithelium at the distal end of the foregut. This outgrowth,

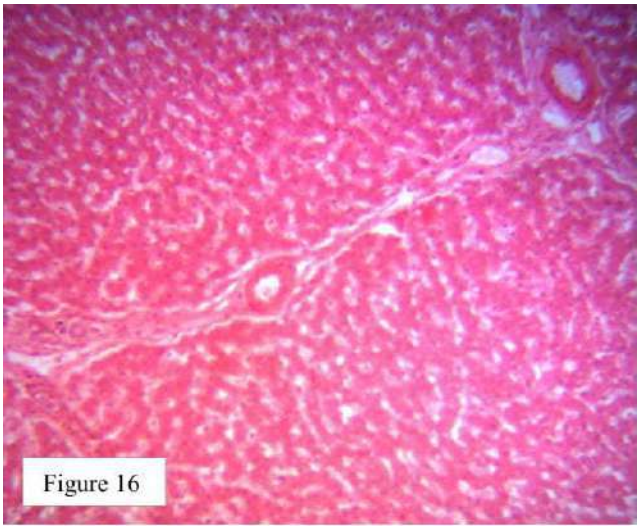

Fig. 16: Right lobe of liver

the hepatic diverticulum or liver bud, consists of rapidly profilerating cells that penetrate the septum transversum.[4]

The liver is reddish brown in colour, although this can vary depending upon the fat content. Obesity is the most common cause of excess fat in the liver (also known as steatosis): the liver assumes a more yellowish tinge as its fat content increases. The texture is usually soft to firm, depending upon the volume of blood and the fat content.[1]

The variations observed in the anatomy of the human liver have been classified as congenital or acquired. Congenital anomalies can be attributed to the following factors: a) separate lobes (considered to be a congenital variation by some anatomists); b) atrophy at some locations in the parenchyma; c) presence of only one lobe; d) presence of multiple lobes, typically involving numerous divisions (up to 16) of the right lobe; e) small lobes; f) peduncular lobes; g) lobes without division; and h) accessory lobes. Acquired changes in liver morphology are represented by the following characteristic features: i) linguiform lobes, ii) costal organ with very small left lobe, iii) deep renal impressions.[5]

Out of the 39 livers studied, 28 specimens (71.79%) were found to be normal. Morphological variations were observed in 11 specimens (28.20%).

On the basis of these variations, the livers were classified into ten groups. Six of these specimens, types 1 to

6, correspond to the morphological types (including the normal type) established by Netter[3] as described in Table 1. The remaining four liver specimens, types 7 to 10 reported inTable 1 of the present study have not been adequately described according to the classification of Netter[3] and were considered as new variant types 7, 8, 9 and 10.

Type 6 showed diaphragmatic grooves (Figure 6). This type of variant has been described previously by Nagato AC et al[2] and Yoshimitsu K et al.[6] These authors considered the diaphragmatic grooves to be accessory hepatic fissures caused by invaginations of the diaphragm. This can also be due to peritoneal fold or non union of segments in foetal life.

Type 7 showed enlarged left lobe (Figure 7). Historically, the liver has been considered to be divided into four lobes by the surface peritoneal and ligamentous attachments. The left lobe is the smaller of the two main lobes, although it is nearly as large as the right lobe in young children. It lies to the left of the falciform ligament with no subdivisions and is substantially thinner than the right lobe.[1] According to Gray and Williams,[7] the right lobe is typically larger and more bulky than the left. On this basis, one liver (2.56%) described as type 7 is considered as a morphological variation because the left lobe was very much larger than the right. Bezerra ASA et al[8] suggested that the reduction in size of the right hepatic lobe and the compensatory increase of the left and caudate lobes may result from pathological processes in patients with schistosomiasis.

Types 8, 9 and 10 of liver specimens with lingular processes and cornu of the left lobe may be due to excessive tissue formed at a localized site in the form of extentions or pressure from the surroundings organs during fetal life causing inhibition of formation of complete left lobe so these processes developed in the area of least resistance.

Histologically, all the specimens were normal according to the description in standard textbooks of histology.[9]

Though distinct morphological types of human liver can be identified in the literature, relatively few studies are available on this topic and detailed descriptions of the different types of anatomical variations are scarce. One reason for this may be associated with a particular difficulty encountered in the present study relating to the characterisation of cadaveric sources in terms of sex, age and previous diseases, all of which may impact on liver morphology.

Some apparent morphological changes detected during advanced imaging examinations may actually be pseudo–lesions resulting from perfusion defects, focal fatty infiltrations and other causes, and may not represent true parenchymatous lesions.[2]

This data suggests that there is a high incidence of anatomical variations in the human liver. No statistical data relating to the frequency of occurrence of livers displaying gross variations in morphological character could be found in the literature in order to serve as a basis for comparison with the studied samples.

5. Conclusion

Though many anatomical variations in the shape of the liver were encountered, histologically all specimens were normal hence the present study suggests that functionally these livers were normal. The possible explanation for gross anomalies could lie in its embryological development. Detailed descriptions of normal and variant liver morphologies can make a significant contribution to understanding the causes of the changes and is a prerequisite for the favourable outcome of a surgical procedure. It is useful for the imaging specialists and surgeons to avoid misinterpretation and misdiagnosis for appropriate planning of the surgical procedures.

Abstract

Background: The placenta is an important organ that acts as a conduit for transporting substances from the mother to the fetus and vice versa. It performs many functions and is intimately related to both the mother and the fetus. Anemia is a leading disorder of pregnancy and is seen to effect >65% of pregnant women in India. It is also a known cause of intra-uterine growth retardation, preterm deliveries, low-birth-weight deliveries, etc. **Objective:** The aim is to study and compare the morphometric and histological changes seen in placentae from normal and anemic mothers. **Methods:** This study was done in the Department of Anatomy of Shri Ram Murti Smarak Institute of Medical Sciences and Research, Bareilly, Uttar Pradesh, India. One hundred and fifty placentae were collected, 75 each from normal and anemic mothers. A thorough morphometric and histological study of the placentae was done, and the results were recorded. **Results:** It was observed that the mean weight, diameter, circumference, and chorionic plate area of the placentae from anemic mothers was significantly reduced in comparison to the controls. Histological study showed that there was a significant increase in pathological changes such as syncytial knots, fibrinoid necrosis, calcification, and medial coat proliferation of blood vessels in samples obtained from placentae of anemic mothers in comparison to the controls. **Conclusion:** It was concluded from this study that maternal anemia has significant consequences on the developing placenta. These morphometric and microscopic changes in placental structure can in turn reduce its function, thus having an adverse effect on fetal outcome.

Keywords: Anemia, morphometry, placenta

Introduction

The placenta is an organ that connects the developing fetus to the uterine wall. As this complex structure is very closely associated with the fetus throughout gestation, its study provides us an accurate record of an infant's prenatal period.

Anemia is the most common nutritional deficiency disorder in the world. According to the WHO guidelines, a level of hemoglobin below 11 g/dl is an indication of maternal anemia. It is a hazardous, hematological disorder and, according to the WHO statistics, is seen in 65%–75% of pregnant women in our country. It contributes significantly to maternal morbidity and mortality.[1]

The placenta is a unique organ as it is both a conduit of oxygen to the fetus as well as an expender of oxygen to support its own metabolism and these two functions are perfectly balanced. In patients with anemia there is an underlying deficiency of oxygen-rich blood, and hence, the amount of available oxygen becomes a very critical factor for the development of the placenta, placental blood vessels, and the fetus.

When pregnancy is complicated by maternal anemia, many pathological changes are bound to occur, which can influence morphometry and histology of the placenta. A reduction in weight, circumference, diameter, area, and histological changes such as infarction, calcification, intervillous thrombosis, and fetal vessel hemolysis occurs and reduce the functional

villous mass. Hypoxia that occurs as a result of prolonged anemia during pregnancy is associated with an increased risk of preterm delivery, intra-uterine growth retardation (IUGR), low-birth-weight baby, unfavorable APGAR scores and various other undesirable effects on the fetus.[2] Thus, placenta is a focus of increasing interest in modern obstetrics because significant pathological changes afflict the placenta often before affecting the fetus. Placental abnormalities can therefore be an "early warning system" for fetal problems. As most perinatal fetal deaths are related to insufficient oxygen supply in utero, the study of the placenta plays a pivotal role in predicting the outcome of future pregnancies and their management.

As anemia in pregnancy is known to have a detrimental effect on the placenta, the present study was undertaken to analyze the spectrum of changes that may occur when pregnancy is associated with this underlying disorder.

The purpose of this study was to evaluate the morphometric and histological changes seen in placentae from anemic mothers and to compare the findings with the control group.

Materials and Methods

This study was done in the Department of Anatomy of Shri Ram Murti Smarak Institute of Medical Sciences and Research, Bareilly, Uttar Pradesh, in association with the Department of Obstetrics and Gynaecology and the Department of Pathology after taking required ethical clearance from the institutional ethical committee. One hundred and fifty full-term placentae were randomly collected over a period of 1 year, from mothers who delivered either vaginally or by cesarean section. Relevant history was taken, and the results of hematological investigations were recorded.

The placentae were classified into the control and study group (anemic group). Under each group, 75 placentae were studied. Placentae from women with single, uncomplicated pregnancies of gestational age between 37 and 41 weeks were included in this study. Placentae from mothers with hemoglobin ≥11 g/dL were taken as control group, while those from mothers with hemoglobin ≤11 g/dL were taken as the study group. Placentae from women with associated obstetric or medical complications of pregnancy, i.e., gestational hypertension, fibroids, retroversion of uterus, cervical cancer, ovarian cysts, venous thromboembolism, etc., or with systemic disorders and chronic maternal illnesses were excluded from the study. Placentae obtained as a result of twin pregnancies were also excluded.

Morphometric and histological examination

The placenta was first inspected, and its various morphometric measurements were recorded. The following parameters of the placenta were then measured: weight, diameter, circumference, and chorionic plate area.

1. Weight was measured in grams by an electronic weighing scale
2. Diameter was measured by a digital vernier caliper. Both maximum and minimum diameters were measured in centimeters up to one decimal point
3. Circumference was measured in centimeters up to one decimal point by a thread which was wound around the entire circumference of the placenta and cut at the point of crossing after one round. The length of the cut thread was measured by stretching it between the two arms of the digital caliper.
4. From the diameter of the placenta, the mean chorionic plate area was also calculated by using the following formula:[3]

$$A = \frac{\pi dL.dS}{4}$$

Where A is area of an ellipse, dL is the largest diameter and dS is the smallest diameter.

For the histological study we obtained full-thickness tissue from the placenta and prepared it for routine H and E. In the light microscopic examination, the placental villi were quantitatively screened for syncytial knots, fibrinoid necrosis, cytotrophoblastic cellular proliferation, calcification, and endothelial changes in blood vessels. All the slides were first observed in low power (×10) and then the presence of the aforementioned parameters was recorded per low power field (per lpf). Three random and different areas of the slide were screened, and the range and mean of the values obtained per low power field was recorded. Histological photographs were taken with the help of an Olympus CX21i compound microscope, which had an attached camera.

A comparison between the control and study group was made by calculating the mean, median with standard deviation and *P*-value for each parameter by using *t*-test.

Results

Morphometric measurements

Table 1 shows the various morphometric measurements of the control and study group. It was observed that in the anemic group; the mean weight, minimum diameter, circumference, and chorionic plate area were reduced in comparison to the control group and this reduction was found to be statistically significant ($P \leq 0.05$). The maximum diameter of placentae from the anemic group was also reduced in comparison to the controls, but this reduction was statistically not significant.

Histological findings

Table 2 shows a comparison between various histological features observed in placentae from both the control and anemic group.

On light microscopic examination of placentae from anemic mothers, it was observed that syncytial knots [Figure 1], fibrinoid necrosis [Figure 2], areas of calcification and medial coat proliferation of blood vessels [Figure 3] were significantly increased in anemic groups in comparison to the controls.

Table 1: Morphometric parameters of placenta in control and study group

Morphometric parameter	Control ($n=75$)		Anameia ($n=75$)		*P*
	Range	Mean±SD	Range	Mean±SD	
Weight (g)	336-584	464.28±50.45	210-600	411.14±83.5	0.002
Maximum diameter (cm)	14.1-20.1	17.13±1.43	11.8-23.1	16.24±2.88	0.1061
Minimum diameter (cm)	13.1-18.1	15.76±1.3	10.4-20.8	14.52±2.81	0.0207
Circumference (cm)	48.2-68.7	57.54±5.45	23.1-64.2	47±8.58	0.001
Chorionic plate area (cm^2)	149.42-272.80	213.35±33.79	96.33-377.17	91.25±72.05	0.0001

Table 2: Histology by hematoxylin and eosin staining per lpf (low power field-×10)

Histological finding by H and E staining per lpf (×10)	Control ($n=75$)		Anameia ($n=75$)		*P*
	Range	Mean±SD	Range	Mean±SD	
Syncytial knots	10-15	12.2±1.49	6-21	13.88±4.23	0.03
Cytotrophoblastic proliferation	4-12	8.11±2.13	4-10	7.71±1.7	0.3883
Fibrinoid necrosis	3-9	6.85±2.25	7-17	10.82±2.13	0.0001
Calcification	2-9	5.71±2.35	9-24	14.11±4.6	0.0001
Medial coat proliferation of blood vessels	4-9	6.02±1.72	8-12	9.51±1.31	0.0001

SD: Standard deviation, H and E: Hematoxylin and eosin

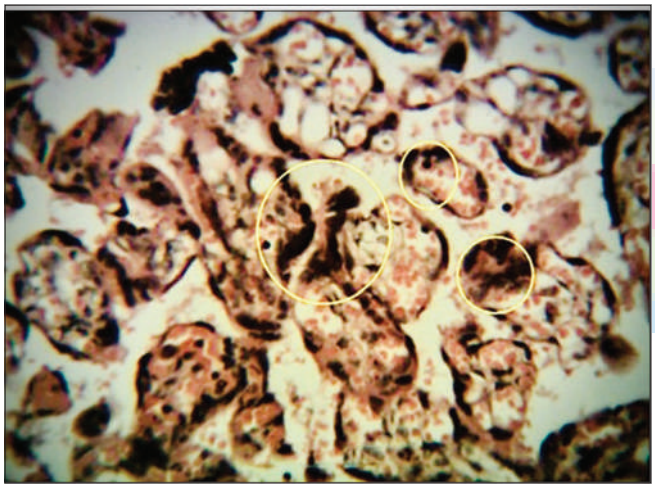

Figure 1: Showing syncytial knots in study group

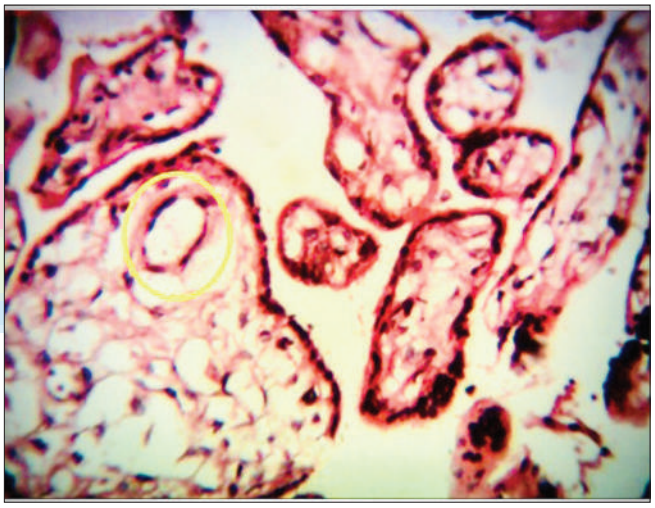

Figure 2: Showing fibrinoid necrosis seen in study group

Cytotrophoblastic cellular proliferation [Figure 4] was slightly reduced in the anemic group in comparison to the controls, but this reduction was not statistically significant.

Discussion

Anemic disorders of pregnancy are one of the leading causes of maternal and perinatal mortality and morbidity. The present study deals with changes in morphometry and histological structure of the placenta in mothers with anemia. A total of one hundred and fifty placentae were meticulously studied. It can be inferred from the results of the present study that the mean of all morphometric parameters of the placenta was reduced in the anemic group in comparison to the controls.

The mean chorionic plate area of anemic group was also reduced in comparison to the controls. This corresponds to a decreased diameter and circumference in the study group in comparison to the controls. It was seen that in mothers suffering from gestational anemia the placental size was smaller as compared to the placentae from normal, healthy mothers.

This overall reduction in the size of the placentae from mothers of the study group indicates that anemia has a detrimental effect on placental development, and it can be attributed to the lower oxygen-carrying capacity of the blood and the resulting hypoxia. Most authors like Rohini *et al*. reported that the mean weight of placentae from anemic mothers was 410 g.[4] This finding was similar to the findings of the present study. Mongia *et al*., who have studied placental morphometry in Indian women and other ethnicities, have also found similar results.[5] But some authors like Godfrey *et al*.[6] and Agboola,[7] who also studied placentae from anemic mothers, reported that anemia and iron deficiency

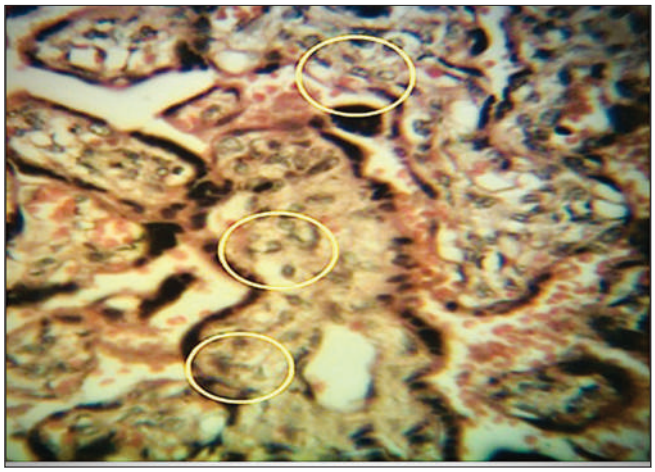

Figure 3: Showing medial coat proliferation of blood vessels in study group

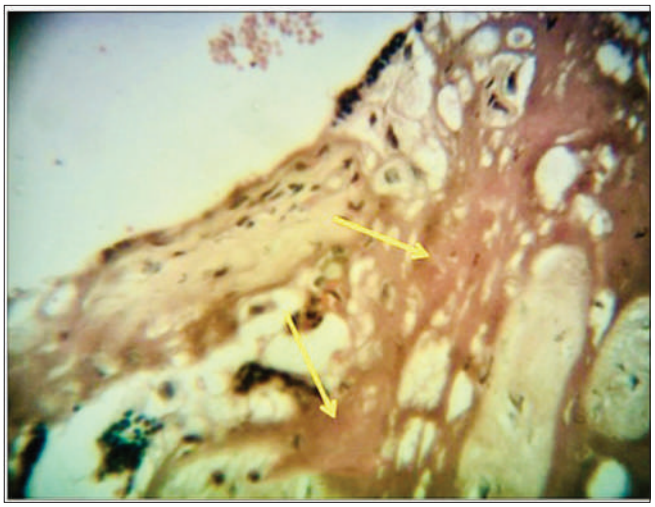

Figure 4: Showing cytotrophoblastic cellular proliferation in study group

during pregnancy were associated with large placental weight and size, and thus, they found a positive correlation between maternal anemia and placental weight. They also observed that placental hypertrophy appeared to be a uniform, proportional, physiological compensatory growth. This was in contrast to the findings of the present study, where placental weight was found to be significantly reduced in anemic group. A review of data published by a few other authors also reveals that hypoxia may initially cause hypertrophy of the placenta, but with the advancement in the pregnancy, i.e., toward term, placental growth retardation is observed.[8,9] This hypotrophy of the placenta may be dependent on the duration, time, and severity of anemia.[10]

One of the main functions of the placenta is that it acts as a barrier between the fetus and the mother by separating the fetal blood vessels from the maternal blood present in the intervillous spaces. The structure of this placental barrier can be observed under a light microscope. The barrier is selectively permeable and allows certain substances such as water, oxygen, hormones, and other nutritive molecules to pass from the maternal blood to the fetal blood vessels and excretory products to pass from the fetus to the mother. The components of the placental barrier from maternal to fetal side are:

a. Syncytiotrophoblast
b. Cytotrophoblast
c. Trophoblastic basement membrane
d. Connective tissue core of the villus derived from the fetus (extraembryonic mesoderm)
e. Basement membrane of fetal capillaries
f. Endothelium of fetal capillaries.[11]

With increasing gestational age, this barrier reduces in thickness and this appears to be a normal change seen with placental maturity. Closer to term, we also observed that the syncytiotrophoblast layer became thin and syncytial knots were increased. The cytotrophoblast layer also reduced and was seen as clumps and fragments. Increased deposition of fibrin was seen on the villus surface as well as in the tunica of the blood vessels. These changes are a sign of placental maturity and are seen in normal placentae, but their increased incidence in placentae from anemic mothers signifies that these changes in the placenta are not proportional to the gestational age.

On histology of placentae from anemic mothers, we observed that there was a significant increase in the presence of calcification, medial coat proliferation of blood vessels, syncytial knots, and fibrinoid necrosis in comparison to the controls. Areas showing fibrinoid necrosis were significantly increased, and fibrin deposit was seen even in the tunica of blood vessels. Fibrinoid necrosis of blood vessels leads to intervillous hemorrhage, which was also observed in few anemic cases but not in controls. Al-Hakeem *et al*.[12] studied changes in placentae from anemic mothers and found an increase in histomorphological abnormalities like thickening of the capillary basement membrane, cytotrophoblastic proliferation, syncytial knots, and fibrosis. Mehrotra *et al*.[13] and Biswas *et al*.[14] reported a similar increase in villous fibrosis and syncytial knots in placentae from anemic mothers. Increased syncytial knots, fibrinoid necrosis, and a reduction in cytotrophoblastic cellular proliferation are all effects of reduced perfusion and oxygen concentration. Tripathi and Sudele[15] and Soni and Nair[16] conducted a similar histopathological study on placentae from anemic mothers, and they found that the areas showing cytotrophoblastic cellular proliferation were significantly increased in the study group in comparison to the controls. This is contrary to our finding, but it is essential that gestational age and severity of anemia be considered before these values can be accurately compared. It is postulated that when the placenta develops in hypoxic conditions like anemia the villi show many changes, including an increase in angiogenesis and terminal capillaries.[17] These changes appear to be a compensatory mechanism to fulfill the needs of the developing fetus. Placental changes characterized by endothelial or vascular abnormalities like medial coat proliferation may present with increased permeability of the vessels, which can even lead to fetal anemia.[18]

These histological changes are also an indicator of placental maturity as the placentae from mothers who delivered postterm (beyond 42 weeks of gestation) usually present with a higher incidence of these features. An early appearance of signs of placental maturity can be a signal for induction of labor and spontaneous preterm delivery. This can be extremely dangerous for a yet under-developed fetus and can explain why anemia is a known and leading cause of preterm delivery, IUGR, and abnormal APGAR scores at birth.

Conclusion

From the various morphometric changes observed, it is concluded that placentae obtained from anemic mothers show a significant reduction in placental size. On histopathological analysis, these placentae also show an increase in signs of ischaemic damage to tissues along with maldeveloped terminal villi. These findings may account for impaired gas and nutrient transfer to and from the fetus in these disorders, thereby resulting in perinatal mortality and morbidity. This also helps us establish that IUGR, abnormal APGAR scores of the baby and preterm deliveries seen in anemic mothers can be caused due to microscopic changes in the structure of the placenta and fetal hypoperfusion. It is essential that the spectrum of placental changes and their effects on the fetus be studied further and evaluated qualitatively to establish such a correlation.

Human Immunodeficiency Virus and Hepatitis B Virus Co-infection in a Tertiary Care Hospital From Rural Area

Milind Davane[1], Bhausaheb Munde[2], Jyoti Jojan[3] and Basavraj Nagoba[4]
Assistant Professor, Department of Microbiology, MIMSR Medical College, Latur[1], Associate Professor, Department of Microbiology, Government Medical College, Chandrapur[2], *Former Assistant Professor, Department of Microbiology, MIMER Medical College, Talegaon Dabhade, Pune[3], Asst. Dean (R&D) and Professor, Department of Microbiology, MIMSR Medical College, Latur, Maharashtra, India[4].*

Abstract:

Background:

The Hepatitis B virus (HBV) and Human immunodeficiency virus (HIV) are devastating viruses that share certain epidemiological characteristics such as risk population and transmission routes. Because of this, HIV positive individuals are at risk of co-infection with Hepatitis B virus. The reports show that co-infection by HIV/HBV causes increased morbidity and mortality as compared to HIV and HBV mono-infection.

Objectives:

The present study was undertaken to determine the prevalence of Hepatitis B virus co-infection in HIV positive patients.

Materials and Methods:

A total of 1000 clinically suspected HIV infected cases attending the Sexually transmitted disease (STD) clinic were selected. The blood samples were collected by taking all aseptic precautions. The serum samples were screened by Comb –AIDS test for HIV and confirmed as per National Aids Control Organization (NACO) guidelines and then HIV positive patients were screened for Hepatitis B surface antigen (HBsAg) marker by immunochromatographic test (Hepacard).

Results:

Out of 1000 clinically suspected cases, 348 (34.8%) were positive for HIV. Out of 348, 186(53.44%) were male and 162(46.55%) were females. Among a total of 348 HIV patients, six cases were found positive for HBsAg. Thus, HIV/HBV co-infection was detected in 1.72% cases in this study.

Conclusion:

The results indicate that the prevalence of co-infection in our area is comparatively lower as compared to other geographical areas.

Received date: 06/05/2019 Revised date: 09/09/2019 Accepted date: 12/09/2019

Introduction:

According to the Joint United Nations Programme on HIV/AIDS (UNAIDS), about 33 million people are infected with Human Immunodeficiency Virus (HIV) worldwide and majority of them live in Asia and Africa. India has the highest HIV/AIDS prevalence in the world with an estimated 5.7 million people living with HIV/AIDS.[1] Hepatitis B is a fatal infection of liver caused by Hepatitis B Virus (HBV). Both HIV and Hepatitis B are transmitted through sexual and percutaneous routes. Thus co-infection of HIV and Hepatitis B virus is common. Hepatitis B is reported to be 50 to 100 times more infectious than HIV.[2] Both HBV and HIV are noxious viruses that share certain epidemiological characteristics such as risk population and transmission routes. Because of this HIV positive individuals are at risk of co-infection with Hepatitis B virus.[3-5] The seroprevalence for HIV and HBV co-infection ranges from 6.3% to as high as 39%.[6-8] The reports show that co-infection by HIV/HBV causes increased morbidity and mortality as compared to HIV and HBV mono-infection. The interaction between HIV and HBV is an important issue which

suggests that HIV/HBV confection has negative impact on liver disease caused by these viruses.[9-10] HIV/HBV co-infected patients are at increased risk of developing cirrhosis, having higher levels of HBV replication, having lower rates of spontaneous resolution of HBV infection and having a higher risk of activation of previous infections.[9,11,12]

Whether HBV affects HIV progression has been a matter of much debate. However there are evidences that suggest that there is faster progression of HIV to AIDS defining illness in patients co-infected with HBV.[13-14]

Center for Disease Control (CDC) and prevention recommends all HIV infected patients should be screened for HBV and those susceptible should be vaccinated accordingly.[15-17]

There are very few studies done abroad as well as in India on prevalence of HBV co-infection in HIV infected patients. Therefore, the present study was undertaken to determine the prevalence of Hepatitis B virus infection in HIV positive patients at Tertiary Care Hospital in Latur District of Maharashtra, India.

Materials and Methods:

This study was conducted in Department of Microbiology, MIMSR Medical College, Latur District, Maharashtra, India from September 2010 to June 2014.

A total of 1000 clinically suspected HIV infected cases attending the Department of Skin and Venereal Diseases (VD) were selected. The blood samples were collected by taking aseptic precautions. Five ml of venous blood samples were collected from the patients. While collecting the blood samples the arm of subject was tied with tourniquet above the elbow joint to make the veins prominent. A vein was selected and cleaned with cotton swab dipped in spirit, and then a sterile 5 ml syringe with needle was used to pierce the vein and collect 5 ml of blood which was transferred aseptically in to a sterile dry plain bottle. The blood was allowed to clot for 30 minutes and centrifuged to get serum sample.

The serum samples were screened by Comb – AIDS test- a Dot immunoassay test that employs the same principle as Enzyme Immuno Assay (EIA) in which the immobilized antigen-antibody complex is visualized by means of color producing (chromogenic) reaction. The test was performed by adding and mixing two drops of sample to each of the wells. The Comb was placed and

sample was incubated at room temperature for 10 min. The comb was rocked in between during incubation. Four drops (0.2 ml) of colloidal gold signal reagent was dispensed into each of another set of unused micro-test wells. The comb was removed and blotted on absorbent material. The comb with the tip pointing down was rocked forward and backward in the wash solution for about 10 times, and then again the tips of the arm were blotted. · The comb then was placed into well containing colloidal gold signal reagent by incubating at room temperature for 10 min. After incubation the Comb was washed again and observed for chromogenic reaction. Presence of pink colored spot in the "test" and "control" area was reported positive for HIV and confirmed as per the Strategy IIB of NACO guidelines and then HIV positive patients were screened for HBsAg marker by immunochromatographic test (Hepacard), which is a one step immunoassay based on the antigen capture, or "sandwich" principle. The test was performed by adding two drops of human serum/plasma specimen into the sample well and allowed to react for 20 minutes. Formation of pink line in test as well as control area was considered as positive.

Results:

Out of 1000 clinically suspected cases of HIV, 348 (34.8%) were positive for HIV. Out of 348, 186 (53.44%) were male and 162 (46.55%) were females. Almost all HIV positive cases were from age group 20-50 years with a negligible number of cases from the age group below 20 years and age group above 50 years. Among the total of 348 HIV positive patients, six cases (1.72%) were found positive for HBsAg. Thus, HIV/HBV co-infection was detected in 1.72% cases.

Discussion:

Though the routes of transmission are same in HIV and HBV infections, the prevalence of co-infection varies from place to place. Different prevalence rates from different geographical areas have been reported in various earlier studies.[23,28,31,35,39] In the present study, a prevalence rate of co-infection was found to be 1.72%. Although this finding of a very low prevalence rate of HBV co-infection with HIV is consistent with studies by Ankur et al.[23] and Hussain et al.[28] and fairly correlates with the findings of these studies, it appears to be very low when compared with various other studies from other countries [31,35,39] and even from other studies from India[22,24,40] who report higher prevalence rates in their studies. The very low prevalence rate of co-infection may be attributed to the differences in the study groups and prevalence of HBsAgin the community in particular geographical area. A great variation in the pattern of HBV/HIV co-infection has been reported in different studies (Table no. 1) indicating that pattern of co-infection varies from place to place.

HIV has a substantial impact on the course and the outcome of HBV disease. The rate of HBV viral clearance is decreased in HIV infected patients after an acute HBV infection. The co-infected patients progress to liver disease more rapidly with a shortened period between acquisition of infection and end stage liver disease.[42,43] The studies show that HBV reactivation and replication are enhanced in co-infected patients.[44]

The effects of HBV infection on progression of HIV disease are less clear. The finding that some HBV products, such as HBV-x protein enhance HIV replication suggesting that HBV could have an impact in HIV progression.[45] However, these findings have not been supported by clinical studies.

Conclusion:

The findings of the present study indicate that the prevalence of co-infection in our area is comparatively lower as compared to other geographical areas suggesting that the prevalence rate of co-infection can change from country to country and even from region to region in same country.

OSPE in Biochemistry - An Assessment Tool for First M.B.B.S. Students as a Prelude to CBME in India

Richa K. Lath[1], Umesh Kumar Pareek[2], Ashish A. Jadhav[3], Aniruddha N. Jibhkate[4] and Milind N. Dudhane[5] Associate Professor[1], Assistant Professor of Biochemistry[2], Additional Professor of Biochemistry[3], Professor of Physiology[4], Professor of Biochemistry[5].Ananta Institute of Medical Sciences and Research Center, Rajsamand, Rajasthan, India[1,2,4,5], All India Institute of Medical Sciences and Research Center, Bhopal, India[3].

Abstract:

Background and Introduction:
The study was undertaken with the anticipation of implementation of CBME in India**.**

Aims and Objectives:
Evaluate Objective Structured Practical Examination (OSPE) as a tool for effective assessment of practical skills in the subject of Biochemistry. To introduce the M.B.B.S. students to OSPE, evaluate the perception of students and teachers towards OSPE and compare OSPE with the conventional approach of practical examination taking into consideration the performance of students in both examinations.

Materials and Methods:
This cross-sectional study was conducted in the department of Biochemistry and included First M.B.B.S. students of the batch 2018-19. After prior sensitization to OSPE, First M.B.B.S. students were assessed by rotation around 10 stations. Later a conventional practical examination was also conducted on the same practical syllabus as OSPE. Students score in both examinations was compared and feedback was taken from the students as well as faculty to gain an insight into their perception about OSPE. The mean scores of the students in both the examinations were compared using student t test with the help of the Microsoft excel 2010 and Graph Pad prism 5 software.

Results and Discussion:
Out of the seventy-seven students who appeared for both OSPE and the conventional examination, twenty-six students scored ≥ 50% marks in OSPE as compared to seventy-five students in the conventional examination. Most of them agreed that OSPE was more focused on learning objective, encouraged learning, and analytical and interpretive thinking by the students, eliminated examiner bias and OSPE should be a part of their practical examination.

Conclusion:
OSPE is an objective and reliable tool for assessment in biochemistry, which helps to improve learning and evaluation of practical skills in biochemistry. With a proper and planned implementation, OSPE can be included in the evaluation system for the subject.

Keywords: OSPE, Biochemistry, CBME, assessment.

Introduction:

Competency based medical education (CBME) is an outcome-based practice of education where assessment plays a pivotal role in its successful pursuit. Since assessment is the driving force for learning, assessment in CBME should provide overall information about acquisition of skills by learner and facilitate learning as well[1,2].

Conventional methods of practical examination are based on viva taken at the end after the students complete the given practical. Thus, the practical is not

performed directly in front of the examiners. There is also examiner and experiment variability, and the students' communication skills which might affect the student's scores[3]. With the realization of the pitfalls in conventional assessment methods, Harden in 1975 introduced an objective structured examination for the assessment of clinical competencies (OSCE), which was later, modified to objective structured practical examination (OSPE) for practical skills. Structured examination can more easily control the examiner/ patient or experimental variables[4]. OSPE in Biochemistry can be used to assess various competencies like performance of simple bedside tests, interpretation of laboratory results, correlation of results with clinical conditions, correlation with theory component etc[5].

With this background, the study was undertaken to introduce M.B.B.S. students to OSPE and also to assess the perception of students and teachers towards OSPE.

Aims and Objectives:

1. To evaluate Objective Structured Practical Examination (OSPE) as a tool for effective assessment of practical skills in the subject of Biochemistry.
2. To introduce the First M.B.B.S. students to OSPE as a method of assessment.
3. To compare the performance of students in OSPE and conventional practical examination based on their scores in each exam.
4. To take an account of the perception and awareness of First M.B.B.S. students and teaching faculty towards OSPE as an assessment tool in Biochemistry.

Materials and Methods:

This cross-sectional study was conducted in the department of Biochemistry in a medical college of Rajasthan. The permission of Institutional Ethics Committee was taken. For the study 150 first year M.B.B.S. students were chosen. A written informed consent was also taken from the students. The students were primed about OSPE before the examination.

The syllabus for OSPE was displayed 15 days prior to conduction of OSPE. A conventional practical examination (CPE) based on same syllabus was also conducted the next week after OSPE.

For OSPE, students were rotated around ten stations. Out of these five were observed procedure stations and five were unobserved response stations. The stations were prepared to assess practical skills, analysis and interpretation of lab results, correlation of results with clinical conditions and demonstration of use of basic laboratory instruments like colorimeter and urinometer. Students were given a time of five minutes to attempt the questions at each station. Two rest stations were also given to students to finish any remaining writing work. For the assessment of OSPE, checklist was prepared beforehand with the mark distribution for each of the stations. At the end of OSPE a feedback was taken from the students. The questionnaire was prepared after extensive literature search and the questions were framed to include the cognitive, psychomotor and affective domains as well as assessment domain. A feedback was also taken from all the faculty members of the department.

Inclusion criteria for the study were students who appeared for both exams. Eighty-one students appeared for OSPE out of whom 4 did not appear for the conventional exam and hence were excluded from the study. The mean scores of the students in both the examinations were compared using student t test with the help of the Microsoft excel 2010 and GraphPad prism 5 software.

Results:

A total of 77 students appeared for both OSPE and the conventional examination. Out of these, 26 students scored $\geq$ 50% marks in OSPE as compared to 75 students in the conventional examination. Comparison of scores in OSPE and conventional exam revealed that students achieved more marks in conventional examination (mean score 29.27 $\pm$ 4.58) as compared to OSPE (mean score 15.74 $\pm$ 6.70) and the difference was statistically significant ($p < 0.001$).

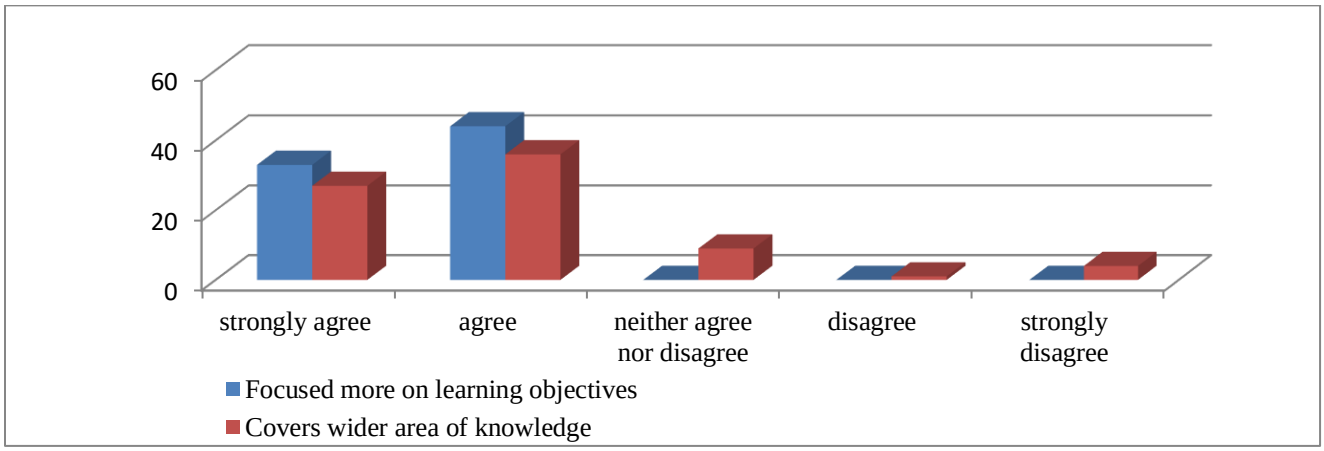

Figure 2: Student's Response for cognitive domain

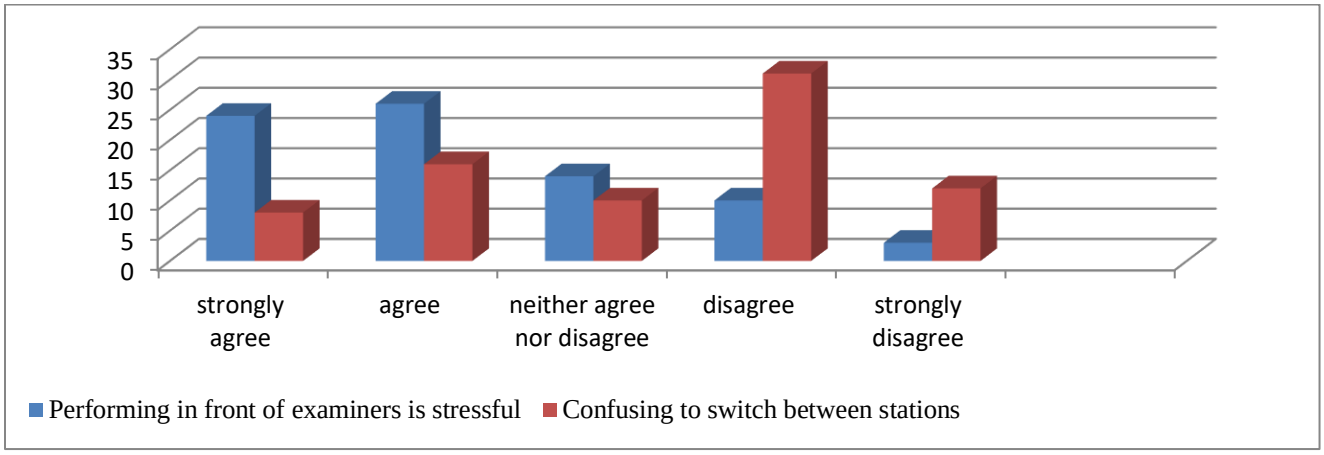

Figure 3: Response for psychomotor domain

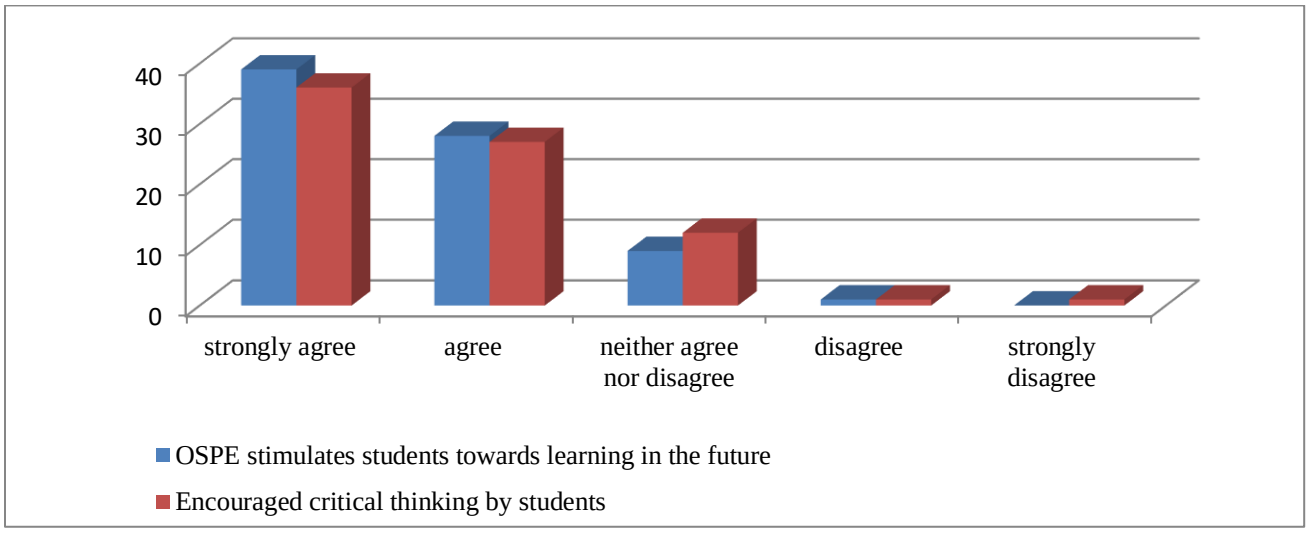

Figure 4: Response for Affective domain

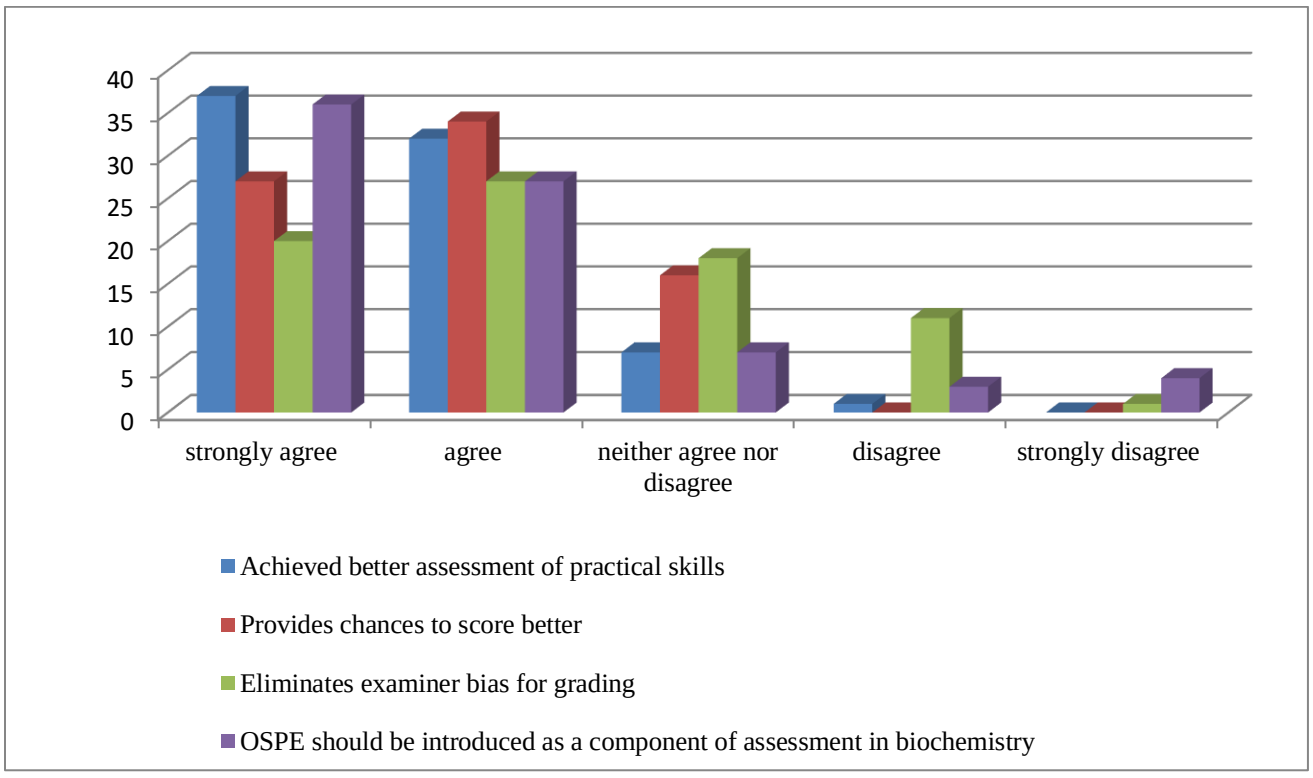

Figure 5: Response for Assessment domain

Table No 1: Student Feedback about OSPE

No.	Questions	strongly agree *n*	agree *n*	neither agree nor disagree *n*	disagree *n*	strongly disagree *n*
1.	Focused more on learning objectives	33	44	0	0	0
2.	Covers wider area of knowledge	27	36	9	1	4
3.	Performing in front of examiners is stressful	24	26	14	10	3
4.	Confusing to switch between stations	8	16	10	31	12
5.	OSPE stimulates students towards learning in the future	39	28	9	1	0
6.	Encouraged critical thinking by students	36	27	12	1	1
7.	Achieved better assessment of practical skills	37	32	7	1	0
8.	Provides chances to score better	27	34	16	0	0
9.	Eliminates examiner bias for grading	20	27	18	11	1
10.	OSPE should be introduced as a component of assessment in biochemistry	36	27	7	3	4

Table No 2: Faculty Feedback about OSPE

No.	Questions	strongly agree *n*	agree *n*	neither agree nor disagree *n*	disagree *n*	strongly disagree *n*
1.	Focused more on learning objectives	5	3	0	0	0
2.	Better assessment of practical skills	6	2	0	0	0
3.	Covers wider area of knowledge	2	5	1	0	0
4.	Provides chances to score better	4	1	1	2	0
5.	Eliminates examiner bias for grading	4	3	0	1	0
6.	Conducting OSPE requires a lot of preparation	5	2	0	1	0
7.	Conducting OSPE is time consuming	5	2	1	0	0
8.	Faculty training in MET is necessary for conducting OSPE	2	4	1	1	0
9.	Present faculty to student ratio is appropriate for implementing OSPE	0	2	0	2	4
10.	OSPE should be introduced as a component of assessment in Biochemistry	3	5	0	0	0

Student's feedback analysis (Table 1) revealed that most of them agreed OSPE was more focused on learning objective and also tested a wider area of knowledge in biochemistry. Most students agreed that switching stations was not confusing, but it was stressful to perform under the direct observation of examiners. They also agreed that OSPE encouraged learning and, analytical and interpretive thinking by the students. Majority of the students felt that OSPE eliminated examiner bias, which could affect scoring, and contrary to their scores in OSPE, most of the students felt that OSPE could help them achieve better score as compared to conventional practical examination. They were of the opinion that OSPE should be a part of their practical examination.

The feedback provided by faculty (Table 2) also revealed that OSPE focused more on learning objectives, with better chances to score by eliminating the examiner bias through the use of preapproved checklist. However, most of the faculty felt that conducting OSPE required more preparation than conventional practical examination, was time consuming and that the present student to teacher ratio was not adequate for OSPE. They also felt that training of faculty in medical education technology was necessary in implementation of newer methods of assessment but still agreed that OSPE should be a part of the practical examinations.

Discussion:

Until last academic session medical colleges in India have directed the training of medical graduates by applying traditional principles of medical education. Traditional curriculum focused more on the learning objectives rather than the outcome and hence conventional assessment methods concentrated mainly on the cognitive aspects with minuscule emphasis on the assessment of psychomotor skills or affective domain. This approach led to a deviation from achieving the goal of yielding first contact physicians for the community. Realization of this scenario ushered the implementation of competency based medical education (CBME) in India[6].

Utilization of a valid and reliable assessment tool to ascertain the achievement of desired competencies by medical students is the need of the hour. OSPE involves rotation of students around multiple stations for the assessment of all learning domains. OSPE helps to reduce the examiner or the experiment variability, by utilizing fixed set of questions, which are assessed using the same checklist by all the examiners. The examiner predefine marking scheme in OSPE and the feedback presented can help improve the teaching strategies as well as the learning process[4].

In the present study, the students' score for OSPE was significantly less than that for conventional pattern of examination. This could be due to the fact that students did not have any prior experience with OSPE. With conduction of repeated OSPE, sharing of checklist with students, their performance can improve. Also, in our study OSPE and the conventional examination were conducted a few days apart as time constraints made it impossible to conduct both on the same day. This could have affected the scores of students to some extent.

At the end of OSPE, feedback was taken from the students to gain an insight into the perception and attitude of students towards OSPE. Feedback plays an important role to ameliorate the standard of teaching – learning methods, assessment tools as well as the performance of the learners[7]. Students' feedback in the present study indicated that majority of them accepted OSPE as a more objective, fair and unbiased tool for assessment. This view has also been supported by other studies[8,9,10]. The students also felt that OSPE helped in assessment of all the three learning domains as opposed to the conventional practical examination.

Out of 77 students included in the study, 50 found that performing in front of the examiners was stressful which could have been due to lack of previous experience with OSPE, lack of knowledge of the procedure and the time restraints for performing it. However, 45 students agreed that there was no confusion while switching stations.

Sixty-seven students agreed that OSPE encouraged learning behavior and 63 students agreed that OSPE encouraged them to critical, analytical and interpretive thinking, which is required of a competent Indian medical graduate. Seventy-three students agreed that OSPE should be introduced as a component of assessment in Biochemistry.

Feedback from the faculty indicated that conducting an OSPE required a lot of prior preparation and was time consuming as opposed to conventional examination but agreed that OSPE should be a part of assessment in Biochemistry. Majority of the faculty agreed that faculty training in Medical Education Technology was necessary for conducting OSPE. This could be to understand the performance level at which assessment has to take place as well as in setting stations fit for the required domain of learning to be assessed. The guidelines put forth by the Medical Council of India (MCI) for Minimum Qualifications for Teachers in Medical Institutions has also made it mandatory for faculty at the post of Associate Professor and above to be trained in medical education technology[11]. Because OSPE involves use of multiple stations, most of our faculty agreed that the present faculty to student ratio was not adequate to implement OSPE. Also, OSPE should be introduced as one of the tools for evaluation in examinations.

Conclusion:

OSPE is an objective and reliable tool for assessment in biochemistry, which helps to improve learning and evaluation of practical skills in biochemistry. With a proper and planned implementation of OSPE, it can be included in the evaluation system for the subject.

ABSTRACT

Background: Vitamin D is a secosteroid hormone and well-known for its classical actions in the maintenance of calcium uptake and bone metabolism. Recently, numerous in vitro experiments demonstrated that 1,25-(OH)2D3, the active form of vitamin D, inhibited the growth and differentiation of human prostate cancer cells.
Aim: To estimate vitamin D level in prostate cancer patients along with increasing risk.
Material & Methods : 100 samples along with control were analysed by cobas e-411 for Vitamin D and PSA.
Results: we have found Higher risk of prostate cancer who having low vitamin D.
Conclusion: it's time to aware people for supplementation of Vitamin D, so we can prevent for the same.

KEYWORDS

Vitamin D, Prostate cancer, PSA, hypovitaminosis

INTRODUCTION:

Deficiency of vitamin D or hypovitaminosis D is widespread irrespective of age, gender, race and geography and has emerged as an important area of research Vitamin D deficiency is prevalent worldwide. This deficiency has many consequences which are still being explored, apart from the well-known skeletal complications. With the consequences of Vitamin D deficiency, namely, autoimmune diseases, cardiovascular diseases, cancer, and tuberculosis being explored. [1]. Vitamin D_3 deficiency continues to be an unrecognized epidemic in many populations around the world. Vitamin D is important for the absorption of calcium, and bone formation and maintenance [2] .The incidence of prostate cancer differs between countries due to coverage of prostate-specific antigen (PSA) screening [3]. patients with advanced-stage or metastatic cancer will ultimately progress to castration-resistant prostate cancer [4]. The mechanisms by which prostate cancer progresses to castration-resistant prostate cancer have been studied extensively [5]. Increasing evidence demonstrates that inflammation plays important roles in the pathogenesis of progression to castration-resistant prostate cancer [6]. A double-blinded clinical study found that vitamin D supplementation reduced prostate specific antigen (PSA) level and enhanced survival rate in patients with prostate cancer [7].

On the other hand, vitamin D receptor (VDR) polymorphisms were associated with the incidence of prostate cancer [7, 8]. Several epidemiological reports showed that men with vitamin D deficiency had a higher risk of prostate cancer compared to men with vitamin D sufficiency [9,10]. Nevertheless, the mechanisms through which vitamin D deficiency elevates the risk of prostate cancer remain unclear. The present study aimed to investigate whether there was an association among prostate cancer, vitamin D status in a hospital-based case-control study.

MATERIALS AND METHODS

A case control study done in Ananta institute of medical sciences and research centre, Rajsamand. During June 2016- November 2016. In the present study, total 50 newly diagnosed patients with prostate cancer were recruited as cases. Prostate cancer was confirmed by histopathology. 50 Controls were recruited from men undergoing physical examination. Vitamin D and PSA done by chemiluminescence immunoassay methodology. method on Cobas e-411 and chemistry (CRP) ,FBG, creatinine, uric acid, T.G., Total Cholesterol by Cobas Intigra 400^{+}. Serum samples of all cases and controls were collected at same season and stored at -20°C.

RESULTS

Biochemical characteristics were analyzed as shown in Table 1, no significant difference in Cr, UA, TG, TCH, fasting blood glucose was observed between cases and controls. As expected, serum T-PSA was significantly increased in patients with prostate cancer as compared with control subjects (Table 2).

Serum 25(OH)D concentration was analyzed in all subjects. As shown in Figure 1A, serum 25(OH)D in patients with prostate cancer was significantly lower than in controls.

Table 1

Parameters	Case(50)	Control (n=50)	P- value
FBG	70±1.2	69.12±.32	0.81 NS
Creatinine	0.87 ±.2	0.96±.31	0.734 NS
Uric acid	3.30±1.1	3.5±1.28	0.086 NS
Triglyceride	125.25±.25	128.35±3.25	0.45 NS
Total cholesterol	155.23±2.3	152.52±2.35	0.93 NS

No significant change

Table- 2

Parameters	case(n=50)	Control(n=50)	P- value
CRP	65.01±2.41	3.01±0.24	<0.0001*
Vitamin D	1.08±.56	8.10±2.16	<0.0001*
PSA	3.70±2.36	15.12±1.25	<0.001*

*Significant change

DISCUSSION

The present study analyzed the association among prostate cancer, vitamin D status. Our results showed that serum 25-(OH) D was reduced in patients with prostate cancer. By contrast, serum CRP, a marker of systemic inflammation, was elevated in patients with prostate cancer. These results provide evidence for the first time that low vitamin D status is associated with inflammation in patients with prostate cancer.

Chronic inflammation promotes metastases and progression to castration-resistant prostate cancer [11, 12]. CRP could predict tumor aggressiveness and potential treatment efficacy in patients with prostate cancer [13]. According to an early report, CRP is an independent prognostic factor for overall survival of patients with castration-resistant prostate cancer treated with docetaxel [14]. A recent study showed that elevated CRP level was associated with poor prognosis in prostate cancer patients treated with radiotherapy [15]. Our results showed that serum 25-(OH)D level was lower in patients with severe prostate cancer than in patients with mild and moderate prostate cancer. By contrast, serum CRP was higher in patients with prostate . These results suggest that low vitamin D status is associated with inflammation and the progression of prostate cancer.

Increasing evidence indicates that vitamin D has an anti-inflammatory activity [16]. These results suggest that inflammation may be a key mediator for prostate cancer progression in patients with low vitamin D status.

The present study has several limitations. First, the present study did not observe whether vitamin D deficiency and inflammation promotes metastasis and progression of prostate cancer. Thus, additional study is required to investigate whether prostatic inflammation promotes prostate cancer in patients with low vitamin D status.

In summary, the present study investigated the association among prostate cancer, vitamin D status and inflammation. Our results showed that serum 25-(OH) D was decreased in patients with prostate cancer. By contrast, serum CRP was increased in patients with prostate cancer.

ABSTRACT

It is important to predict the serum thyroid hormones level in females during infertility to prevent its occurrence later on. In this study, we studied serum thyroid hormones and menstrual irregularities during infertility. **Method :** A case control study was performed in 90 infertile patients with menstrual irregularities and 50 healthy matched women. Three biochemical parameters were measured in serum, hormones triiodothyronine (T3), tetraiodothyronine (T4) and serum thyroid stimulating hormone (TSH) by TOSOHAIA-360, immunoassay method. **Result :** Serum T3, T4 and TSH level were statistically highly significant in infertile women. Serum thyroid stimulating hormone level was found at higher side in infertile women. **Conclusion :** High incidence of hypothyroidism was found in infertile women and it shows a positive correlation with menstrual disorder.

Introduction : Mild or subclinical hypothyroidism is characterized by normal serum free thyroxin concentrations with elevated serum thyroid stimulating hormone concentrations.[1] The prevalence of hypothyroidism in the developed world is about 4-5% [1,2] The prevalence of subclinical hypothyroidism in the developed world is about 4-15% [3,4] In a developing and densely populated country like India, communicable diseases are priority health concerns due to their large contribution to the national disease burden[5]. In India, hypothyroidism was usually categorized under the cluster of iodine deficient disorders (IDDs), which were represented in terms of total goiter rates and urinary iodine concentrations, typicallyassessed in school-aged children[6,7,8]. Ever since India adopted the universal salt iodization program in 1983 [12] there has been a decline in goiter prevalence in several parts of the country, which were previously endemic [13-15]. In 2004, a WHO assessment of global iodine status classified India as having 'optimal' iodine nutrition2[6,7] with a majority of households (83.2% urban and 66.1% rural) now consuming adequate iodized salt[8,9] India is supposedly undergoing a transition from iodine deficiency to sufficiency state. A recent review of studies conducted in the post-iodization phase gives some indication of the corresponding change in the thyroid status of the Indian population[2]. Prevalence of hypothyroidism is 2-4% in women in the reproductive age group. Hypothyroidism can affect fertility due to anovulatory cycles, luteal phase defects, hyperprolactinemia, and sex hormone imbalance. Thyroid hormones are closely interacting through the women's reproductive hormones (estrogens and progesterone) to defend normal role of the ovaries along with maturation of egg (oocyte) .[2] Hormones are liable for maintain mood, reproduction , be asleep, sexual characteristics drive, and ability to switch stress, now to name a few function.[3] The above study undertaken shows a definite rise in serum thyroid hormones level and cases of infertility. Therefore, in this study, we examined serum thyroid hormone level in women during infertility with menstrual irregularities.

MATERIAL AND METHOD: This study was conducted in Annanta Institute of Medical Sciences, Udaipur (southern part of Rajasthan, Indian city) on patients of 2o-45 years of age of infertile women with irregular menstrual cycle, attending the out patients department of gynecology and obstetrics in collaboration with the department of biochemistry. 90 infertile women were included in this retrospective study with 50 healthy matched control women. Blood sample were collected by aseptic technique As per our clinical laboratory procedure, serum was separated from venous blood of fasting subjects and analysed within two hours of collection. The serum separated from the sample was analyzed for following parameters. Triiodothyronine (T3), tetraiodothyronine (T4), thyroid stimulating hormone (TSH) by cobas e-411 Immunoassay method . All results were expressed in mean±S.D. Difference between mean were calculated by student't' test. The level of significance was set as p< 0.05. Statistical analysis was performed using Graph Pad Prism version 5.00 for Windows, Graph Pad software, San Diego California USA, www.graphpad.com.

RESULTS: All women were in the age group of 20-45 years, Table 5 shows the menstrual disturbances with hypothyroidism in infertile women. Different type of menstrual disturbances like amenorrhea, oligomenorrhoea, menorrhagia and polymenorrhoea shown in table 5 , Out of 90 patients with irregular menstrual cycle only 15 had amenorrhea, of these only six (6) had hypothyroidism. Forty five (45) patients had oligomenorrhoea out of them only 16 had hypothyroidism. Twelve and thirteen (16, 14) patients had menorrhagia and polymenorrhoea, respectively. Out of them only 8 and 9 had hypothyroidism. Table 2 shows T3, T4 and TSH level in healthy control age matched patients. In control the mean value for T3, T4 and TSH were 1.35±0.32 ng/ml, 7.50±1.65 µg/dl and 2.12±1.03 µg/ml, respectively. Table 3 shows the serum T3, T4 and TSH level in infertile women, the values were found to be 0.90±0.34 ng/ml, 7.±1.68 µg/dl and 5.83±6.18 µIu/ml, respectively. On statistical analysis serum T3 and TSH level in these women were found to be statistically significant (table 4). P-value for serum T3 is found to be 0.05 and TSH p< 0.01 ,respectively. These were statistically highly significant. More than half of hypothyroid patients have menstrual irregularities and one third of sub fertile patients have thyroid disease.

TABLE 1

THYROID PROFILE IN DIFFERENT MENSTRUAL DISTURBANCES

Total case	hypothyroid	Percentage
90	35	38.88%

T3, T4 & TSH LEVEL IN NORMAL HEALTHY CONTROL GROUP WOMEN (n=50)

Hormones	Normal range	Mean ± Sd
T3 ng/ml	0.79-1.58	1.35± 0.32
T4 ug/dl	4.0-11.0	7.5±1.65
TSH uiu/ml	0.39-5.55	2.2±1.03

TABLE-3

T3 , T4 AND TSH LEVEL IN INFERTILE WOMEN WITH MENSTRUAL IRREGULARITIES (n=90)

Hormones	Normal range	Mean ± Sd
T3 ng/ml	0.21-2.4	0.90±0.34
T4 ug/dl	2.1-20.0	7.9±1.68
TSH uiu/ml	0.08-37.0	5.83± 6.18

15	Amenorrhea	6	40%
45	Oligomenorrhoea	16	35.55%
16	Menorrhogia	8	50%
14	Polymenorrhoea	9	64.28%

DISCUSSION: Infertility is defined as the failure of a couple to achieve a pregnancy despite one year regular unprotected sexual intercourse [9] . Although it has been proved that for normal sexual function , thyroid secretion of T3 , T4 need to approximately normal. Thyroid hormones have profound effects on reproduction and pregnancy. Thyroid dysfunction is implicated in a broad spectrum of reproductive disorders, ranging from abnormal sexual development to menstrual irregularities and infertility [9 . 14.] This study was demonstrated increased thyroid stimulating hormone level in infertile women. Serum thyroid level also affected by diet. We also found that menstrual pattern was abnormal in majority of infertile women. Our study is correlated with the study of Shalvev et al., (1994) [10]. Shalvev et al., studied the routine thyroid function test in infertile women and reported the low incidence of hypothyroidism in the pregnant patients is related to the close association between infertility and hypothyroidism 4 .. Usha R. Sharma reported hypothyroidism with menstrual irregularities. Our incidence of hypothyroidism is more probably because of case of infertility was not sub divided in to primary and secondary. In hypothyroidism, there is decreased synthesis of factors VII, VIII, IX, and XI and estrogen break through bleeding secondary to anovulation, which may explain the frequent, prolonged, and heavy menstruation [12] . Our study was also correlated with the study of Hassle et al., (1958), singh et al., (1990), and agarwal et al. (1994) [13,15]. Menon et al., (1995) studied menstrual dysfunction and thyroid disease and reported that there are contradictory reports regarding the types of menstrual disturbances seen in hypothyroidism and paucity of information in the Indian literature on the subject [10,13] . Our study has some limitations. It is a retrospective study which is inferior to prospective studies when the associations between different variables are to be ascertained. Our study is limited only to Women between 20 to 45 years in age. A wider range of age would have been more useful in gauging the distribution of the studied parameters in the population. A high incidence of hyperprolactinemia was found in infertile women and a positive correlation was found between hyperprolactinemia and hypothyroidism. [12,16]

CONCLUSION: The combination of analyzed serum thyroid hormone level and menstrual irregularities were important for infertility cases and useful for the prediction of infertility. So they can treated according to medically.

EFFECT OF MUSHROOM DIET ON WEIGHT GAIN OF ALBINO RATS

Biochemistry

KEYWORDS: Oyster mushroom, *Pleurotus sajor-caju*, mycelium, protein

ABSTRACT

Mushrooms are known for good quality of protein; therefore *Pleurotus sajor-caju* was selected to study the essential amino acid content and the effect of supplementation of *Pleurotus sajor-caju* on growth of albino rats. Rats were randomly assigned on diet containing mushroom fruiting and mushroom mycelium for a period of 30 days. On every 10th day, animals were weighed and their diet intake, remnant food and protein intake were measured. The result showed phenylalanine, methionine, tryptophan, threonine, isoleucine, lysine and histidine values of mycelium found significantly more than fruiting. In animal experiment values showed significant difference in body weight between control and experimental groups. Study concluded that the feeding of mushroom fruiting and mushroom mycelium diets helped to gain weight of albino rats because of then excellent nutritional composition.

INTRODUCTION

There has always been lack of harmony between the rapidly growing world population and the adequate supply of protein rich foods in the human diet. The mushrooms, yeast and algae are frequently mentioned as an alternative source for food. Mushrooms have been valued throughout the world as both food and medicine for thousands of years (Lindequist *et al.,* 2005; Wright 2004; and Tribe *et al.,* 1973).

Mushrooms are considered as a good source of protein, vitamins and minerals (Jiskani, 2001). *P. ostreatus* and *Pleurotus sajor-caju* are contain protein (27.4% and 26.9% respectively), carbohydrate (40.75%) and low lipid (5.4 % and 6.2 %) on dry weight basis (Dhonda *et al.*, 1996; Rai *et al.* 1988). Chang and Miles (1989) have suggested that the protein in mushroom, in general, is about twice that in asparagus and cabbage, and 4 and 12 times those in oranges and apples, respectively.

All the essential amino acids required by an adult are present in mushroom (Bisaria *et al.*, 1987). Lintgel *et al.* (1994) reported the digestibility of mushroom protein to be as high as 72-83 per cent. Quality of mushroom protein is far superior to the vegetable proteins and it is as good as or just inferior to animal protein because of presence of essential amino acids (Crisan and Sands, 1978; Bano and Rajarathnam, 1982; Chang and Miles, 1989). Quality of protein is nutritionally more important than its quantity. Requirement of protein is infact the requirement of amino acids. Human body is incapable of producing essential amino acids. Mushrooms are well recognized for their protein quality. Keeping this in view fruiting and mycelium of oyster mushroom were analyzed for its essential amino acids content and the diet supplemented with *Pleurotus sajor-caju* was selected to feed albino rats to know the growth effect.

MATERIAL AND METHODS

The present study was conducted during 2006-2007 in the Department of Home Science, Sant Gadge Baba Amravati University, Amravati. Oyster mushroom spp. *Pleurotus sajor-caju* was selected because it is grown commercially in central India and cost of cultivation is low. Fruiting of oyster mushrooms was cultivated by polybag technique and mycelium was grown on agar-agar media. Fruiting and mycelium of oyster mushroom were harvested from bags and media, respectively. Both were dried at 32^{0}C temperature in the incubator. Fruiting and mycelium were ground to form fine powder. Powders were stored in airtight container. Fruiting and mycelium of oyster mushroom were subjected to analyzed essential amino acids by paper chromatography method (Thimmaiah, 1999). Oyster Mushroom diets were prepared out of fruiting and pure mycelium. Oyster mushroom diets (as shown in table 1) were fed to albino rats to study the effect on weight of albino rats.

About thirty male albino rats were obtained from Department of Biochemistry, Rastra Sant Tukdoji Maharaj Nagpur University, Nagpur. The weight of rats was between 50 to 60 grams and age was between 40 to 45 days. Rats were randomly divided to in five groups. Each group had 6 rats. Control diet was fed to first group of rats and rest four groups were kept on experimental diets. At the beginning of the experiment, all rats were fed with standard diet (Swaminathan, 1999) for one week. The observations about diet provided and left over were recorded. The duration of feeding experiment was 30 days, on every 10th day rats were weighed. Their diet intake, remnant food and protein intake were measured. The composition of control and experimental diets is given in table 1. Control diet does not contain mushroom fruiting or mycelium. Diet 1 and 2 comprise control diet and 1 and 2g oyster mushroom fruiting (OMF) respectively. Diet 3 and 4 contain control diet and 1and 2g oyster mushroom mycelium (OMM) respectively. Water was given in adlibitum.

Table 1: Composition of control and experimental diets

S. No.	Ingredients (g)	Control diet	Experimental diets

RESULTS AND DISCUSSION

Oyster mushroom was analyzed to find out essential amino acids and estimated mean values are given in the table 2.

Table 2: Essential amino acids (% crude protein) in fruiting and mycelium of oyster mushroom

S. No.	Essential amino acids	Fruiting Mean ± SD	Mycelium Mean ± SD	't' value
1	Phenylalanine	4.00 ± 0.10	6.50 ± 0.10	10.00*
2	Valine	5.10 ± 0.10	4.30 ± 0.28	01.40
3	Methionine	2.20 ± 0.10	2.60 ± 0.37	02.00
4	Tryptophan	1.50 ± 0.10	2.10 ± 0.10	03.33*
5	Threonine	5.10 ± 0.10	7.50 ± 0.10	08.06*
6	Isoleucine	3.40 ± 0.10	4.20 ± 0.11	05.80*
7	Leucine	6.50 ± 0.10	5.20 ± 0.10	05.90*
8	Lysine	6.40 ± 0.10	7.00 ± 0.11	01.66
9	Histidine	2.10 ± 0.10	2.50 ± 0.01	00.86

* Significant at 0.05 level of probability

The fruiting and mycelium contained all essential amino acids but in varying amount. Fruiting contained 4.00 per cent and mycelium contained 6.50 per cent phenylalanine. It reveals that mycelium found to be better than fruiting in respect of phenylalanine which could be seen from the significant 't' value (10.00) at 5 per cent level of significance.

Valine present in fruiting and mycelium found to be 5.10 and 4.30 per cent, respectively. However, 't' value (1.40) reveals that there was no significant in the content of valine in fruiting and mycelium. Fruiting contained 2.20 per cent and mycelium 2.60 per cent methionine. This shows that both fruiting and mycelium were similar in methionine content, as could be seen from non significant difference between fruiting and mycelium at 5 per cent level of probability.

Fruiting and mycelium contained 1.50 per cent and 2.10 per cent tryptophan, respectively. Mycelium found to be better than fruiting in respect of tryptophan content as 't' value shows significant difference between fruiting and mycelium at 5 per cent level of significance.

Fruiting contained 5.10 per cent threonine and in mycelium it was found to be 7.50 per cent. It shows that mycelium found to be better source of threonine than fruiting as significant difference could be found between fruiting and mycelium at 5 per cent level of probability (t = 8.06).

Isoleucine present in fruiting was 3.40 and 4.20 per cent in mycelium. It indicates that the mycelium found to be better in isoleucine than fruiting, as 't' value (5.80) found to be significant at 5 per cent level of probability. Fruiting contained 6.50 per cent and mycelium contained 5.20 per cent leucine. Fruiting found to be better than mycelium in respect of leucine as significant difference could be noticed from the 't' value (5.90).

Fruiting contained 6.40 per cent lysine and mycelium contained 7 per cent lysine. Though mycelium showed high amount of lysine than fruiting but 't' value showed no significant difference between fruiting and mycelium and thus both are at par as far as lysine content is concerned.

Fruiting contained 2.10 per cent and mycelium contained 2.50 per cent histidine. Both fruiting and mycelium contained similar amount of histidine as no significant difference could be noticed (t = 0.86).

Animal experiment

The observed values of feeding experiment about total diet intake, total protein intake and the total gain in body weight on 10th, 20th and 30th day are given in tables 2, 3 and 4, respectively.

Table 2: Mean diet intake, protein intake, weight gain of albino rats on 10th day

S. No.	Diets	Protein g/100g diet	Actual diet intake (g) Mean ± SD	Actual protein intake (g)	Weight gain (g) Mean ± SD
1	Control	22.12	102.08 ± 2.91	22.67	22.50 ± 2.12
2	1g OMF	22.54	102.03 ± 1.67	22.99	22.58 ± 1.02
3	2g OMF	22.87	104.03 ± 2.95	23.79	27.24 ± 2.43
4	1g OMM	22.68	102.88 ± 2.50	23.33	24.50 ± 2.32
5	2g OMM	23.15	104.12 ± 4.02	24.10	29.18 ± 1.16

Data in table 2 indicates that the gain in body weight of rats kept on experimental diets was better than control diet. It was noted that the weight gain of rats fed on 2g OMF (27.24 ± 2.43) and 2g OMM (29.18 ± 1.16) was better than 1g OMF (22.58 ± 1.02) and 1g OMM (24.50 ± 2.32) diets. It was also observed that the gain in weight of rats fed on diet 1 and 2 comprise OMM was better than the diets 3 and 4 contains OMF. The results thus lead to the conclusion that higher the content of mushroom, better the weight gain. However, mushroom mycelium was found effective than the fruiting of oyster mushroom.

Table 3: Mean diet intake, protein intake, weight gain of albino rats 20th day

S. No.	Diets	Protein g/100g diet	Actual diet intake (g) Mean ± SD	Actual protein intake (g)	Weight gain (g) Mean ± SD
1	Control	22.21	110.12 ± 4.28	24.45	27.18 ± 3.51
2	1g OMF	22.54	112.02 ± 2.10	25.24	28.01 ± 2.51
3	2g OMF	22.87	118.16 ± 5.02	27.02	31.21 ± 1.15
4	1g OMM	22.68	112.78 ± 1.75	25.57	30.04 ± 1.52
5	2g OMM	23.15	115.21 ± 2.04	26.67	33.50 ± 2.64

Data in table 3 indicates that the highest weight gain of albino rat (33.50g) was observed in 2g OMM diet. Rats kept on control diet (27.18g) and 1g OMF diet (28.01g) showed low weight gain. The results showed that oyster mushroom mycelium was found better in increasing the body weight of albino rats and followed by OMF and OMM diets.

Table 4: Mean diet intake, protein intake, weight gain of albino rats on 30th day

S. No.	Diets	Protein g/100g diet	Actual diet intake (g) Mean ± SD	Actual protein intake (g)	Weight gain (g) Mean ± SD
1	Control	22.21	130.10 ± 2.32	28.89	29.01 ± 1.73
2	1g OMF	22.54	131.12 ± 3.98	29.55	28.50 ± 3.05
3	2g OMF	22.87	136.22 ± 3.23	31.15	33.48 ± 2.00
4	1g OMM	22.68	132.18 ± 2.05	29.97	31.50 ± 1.52
5	2g OMM	23.15	135.61 ± 4.01	31.39	36.11 ± 3.00

Perusal of data in table 4 reveal that the highest weight gain of albino rat (36.11g) was found in 2g OMM diet, relatively protein intake was 31.39g. One gram OMF supplemented rat group showed lower weight gain (28.50g) than control group (29.01g) but 2g OMF supplemented group showed better weight gain (33.48g) than 1g OMF fed group. The results thus lead to conclude that weight gain of rat fed on OMM diet was better than the OMF diet. As the amount of mushroom increases weight also increases. However, mushroom mycelium diet were found effective than the fruiting diet.

The data in respect of mean weight gain of albino rats on 10th day, 20th day and 30th day of control and experimental diets (1g and 2g OMF and OMM diets) have been presented in table 5 for comparison.

Table 5: Weight gain (g) of albino rats (control with 1g and 2g doses of fruiting and mycelium each)

S. No.	Days / Diets (n=6)	10th day	20th day	30th day	1st – 30th days
1	Control	22.50	27.18	29.01	78.69
2	1g OMF	22.58	28.01	28.50	79.09
3	2g OMF	27.24	31.21	33.48	91.93
4	1g OMM	24.50	30.04	31.50	86.04
5	2g OMM	29.18	33.50	36.11	98.79
	'F' Test	33.00*			

* Significant at 0.05 level of probability Two way ANOVA was applied for testing the significance of difference of means of control and experimental diets (1g and 2g OMF and OMM diets each) and data obtained have been presented in table 5.

Table 5 reveals that on 10th day the diet intake of albino rats were low, therefore, showed low weight gain. The plausible reason for low consumption of diet was albino rats were not accustomed to the diets. On 20th and 30th day, more weight gain was observed because of increased intake of diet and relative increase in protein intake. Overall weight gain pattern reflects that as diets comprising oyster mushroom increases body weight also increases. *In vivo* proteins are required for tissue development and oyster mushroom comprises good amount of protein. The 2g OMF and 2g OMM diets fed groups showed better weight as compared to 1g OMF and 1g OMM diets. Significant differences were found between weight gain of albino rats fed on different diets.

The quality of food protein depends upon its amino acid composition, especially that of essential amino acids. *In vivo* essential amino acids perform many functions but lysine, leucine, valine and histidine are especially required for growth and as such oyster mushroom comprise these four amino acids in good quantity as reported by Rai (1995).

Results show that the quality of protein depends on presence of all essential amino acids in food; as such oyster mushroom mycelium and fruiting contained all essential amino acids. The mean values of phenylalanine, tryptophan, threonine and isoleucine indicate that the content of these amino acid was definitely higher in mycelium than fruiting. Whereas, the fruiting of oyster mushroom definitely contained higher amount of leucine than the mycelium. The results of the animal experiment proved that the supplementation of oyster mushroom diets showed significant weight gain of albino rats. Thagumanaven and Maniekam (1980). Too observed weight gain in rats fed on *Pleurotus sajor-caju* due to its high digestibility. Similar result was also observed by Samajpati (1979).

CONCLUSION

Present investigation proved that the Oyster mushroom fruiting and mycelium contribute all essential amino acids. Phenylalanine, methionine, tryptophan, threonine, isoleucine, lysine and histidine values of mycelium found significantly more than fruiting. The supplementation of oyster mushroom helped to gain weight of albino rats because of its excellent nutritional composition.

ABSTRACT

Background: Breast cancer is a nonexistent entity for a majority of population till a near and dear one suffers from it.
Introduction: Breast cancer is now the most common cancer in most cities in India, and 2nd most common in the rural areas.
Material and Methods: This prospective study was carried out in Obstetrics and Gynecology, oncology and biochemistry department of Annanta institute of medical sciences, Udaipur ,India. 100 subjects with 100 controls were enrolled for the study.
Results: we have found decreased level of antioxidant in patients in comparison to control.
Conclusion: Awareness with supplementation of natural antioxidant is beneficial to prevent the risk of Brest cancer

KEYWORDS

Breast cancer, cancer, antioxidant vitamin C, vitamin E.

INTRODUCTION:

Breast cancer is now the most common cancer in most cities in India, and 2nd most common in the rural areas.[1] one fourth (or even approaching one thirds) of all female cancer cases are breast cancers. The most important reason being lack of awareness about breast cancer and screening of the same; more than 50% patients of breast cancer present in stages 3 and 4, and outcome is not as good as earlier stages, however aggressive the treatment may be. The western nations have achieved a steadily improving and good survival mainly because of screening of breast cancer**.** Out of every 100 breast cancer patients, 2% were in 20 to 30 years age group, 7% were in 30 to 40 and so on. 69% of the patients were above 50 years of age. Presently, 4% are in 20 to 30 yrs age group, 16% are in 30 to 40, 28% are in 40 to 50 age group. So, almost 48% patients are below 50.[2,3] An increasing numbers of patients are in the 25 to 40 years of age, and this definitely is a very disturbing trend. Of course, one particular reason for higher numbers of younger patients is our population pyramid, which is broad at the base and middle and narrow at top, which means that we have a huge population in the younger age group and much lesser in older age group. [4] In the year 2012, there were about 2,32,000 breast cancer cases reported in the US, whereas in India, 1,45,000 new cases were diagnosed. This implies that, though, because of India's population, the percentage of total women affected seems less, the breast cancer burden in India has almost reached about 2/3rds of that of the US and is steadily rising.[5,6]

Oxidative stress is a biochemical condition that occurs when intracellular antioxidants are unable to neutralize pro-oxidants such as reactive oxidant species (ROS). These ROS damage membranes, DNA, lipids, proteins, and carbohydrates, eventually causing cell injury and death. Vitamin C and vitamin E are natural antioxidant. They have many biological functions, antioxidant function, including enzyme activities. They also act on immune function and reduce the risk of breast cancer. [7]

Antioxidants counteract free radicals and prevent tissue and organ damage. Although antioxidants may play a role in the primary prevention of cancer by reducing the oxidative modification of DNA. Till date a very few studies have done in antioxidant and breast cancer relationship in this part of India. So we have planned this study.

MATERIALAND METHODS:

Study setting, study type: This prospective study was carried out in Obstetrics and Gynecology and department of Biochemistry in Annanta institute of medical sciences, Udaipur.

Study participants & study period: women admitted in gynecology and cancer department between March 2017 –September 2017 in the hospital were examined. Blood pressure was measured by mercury sphygmomanometer in reclining position in right brachial artery. Three readings were taken at 10 minutes interval. Participants having average systolic blood pressure ≥ 140 mm hg and/or diastolic blood pressure ≥ 90 mm Hg were included in the study.

EXCLUSION CRITERIA: Patients with history of hyperuricemia, liver diseases, diabetes, renal diseases, cardiovascular illness, and symptomatic infectious diseases , previous cancer history, were excluded.

Sample size and sampling: 100 subjects with 100 controls were enrolled for the study.

Data collection: After enrollment participants were grouped healthy control and patients with breast cancer. Informed consent was taken from all the participants. The history of all participants was taken. Blood samples of participants were taken from right or left cubital vein and collected in plain and citrate tubes.

Serum level of vitamin C was done by NATELSON method, and read at 520 nm by colorimeter.

Serum level of vitamin E was done by BAKER & FRANK method read at 520 nm.

STATISTICALANALYSIS:

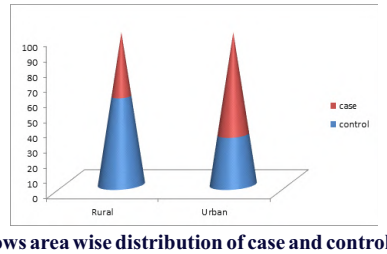
We used unpaired" test for comparing the mean level of uric acid, LDH, AST, ALT with maternal outcome. p value < 0.05 was considered statistically significant.

RESULTS:

In this study we have found a statically significant difference level of serum antioxidant in case and control. We have distributed them according to area, marital status, smoking habit and side of Breast having cancer. Then we have estimated serum Vitamin C and Vitamin E level in these groups.

Table-1 Area wise distribution among case and control

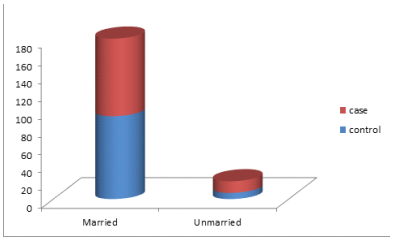
	Rural	Urban	Total
control	58	33	100
case	42	67	100



Figure; 1 shows area wise distribution of case and control

Table-2 Marital status of case and control

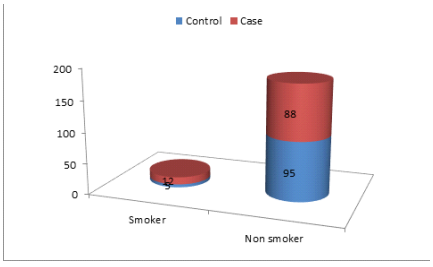
	Married	Unmarried	Total
control	93	07	100
case	87	13	100



Figure; 2 shows marital status of case and control

Table-3 Smoking status among case and control

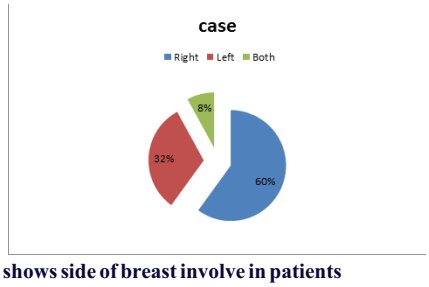
	Smoker	Non smoker	Total
Control	5	95	100
Case	12	88	100



Figure; 3 shows distribution of case and control according to history of smoking habit.

Table-4 Side of breast involve in patients

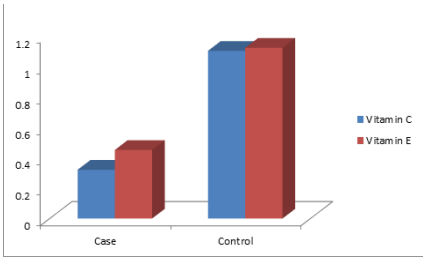
Side involved	case
Right	60
Left	32
Both	08
Total	100



Figure; 4 shows side of breast involve in patients

Table-5 Antioxidant level in case and control

Antioxidant	Case	Control	P-value
Vitamin C	0.32± 0.12	1.10±0.02	<0.0001
Vitamin E	0.45±0.13	1.12 ±0.11	<0.0001



Figure; 5 Shows level of serum antioxidant in case and control

DISCUSSION:

we have determined the level of natural antioxidants in patients and control and then compared it. We have found a strong association between case and control in serum antioxidant level. We have found lower level of vitamin C and E in cases in comparison to control.

In Table 1 we have found distribution of case and control according to their area, main difference in ratio is their lack of awareness of breast cancer in these patients. Table-2 shows marital status of patients. Breast cancer not only affects patients health even it also affect their personal relationship.

Table-3 shows smoking status of patients, Tobacco smoke contains thousands of chemicals, many of which are known to be mammary carcinogens. Although not initially thought to be a tobacco-related cancer, over the last several decades evidence has been accumulating on the role of both active smoking and secondhand smoking in the etiology of breast cancer.[8] Table-4 shows side of Brest in patients.

Table -5 shows level of antioxidant in case and control group. Cancer cells operate under a high level of oxidative stress, due to high baseline levels of reactive oxygen species, oncogenic transformation, and metabolic reprogramming.[9] Oxidative stress occurs due to imbalance between the production of free radicals [superoxide anion (O2 -), hydrogen peroxide (H2O2), hydroxyl radical (OH-), nitric oxide (NO), and more] and their elimination by antioxidant defense mechanisms [superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), among others], which induces cell damage caused by lipid peroxidation generating derangement and loss of function and integrity of the cell membrane, as well as DNA damage, promoting genomic instability and cell proliferation, thereby increasing the somatic mutations and neoplastic transformation.[10,11.]

Ascorbic acid (vitamin C) has been widely used in the treatment and prevention of cancer; nevertheless, the clinical results are still inconclusive. At low concentrations, it has an antioxidant role, preventing oxidation, which induces apoptosis. However, its high content can increase the production of ATP (generated by mitochondria) inducing apoptosis in tumor cell lines, via a pro-oxidant mechanism.[11] Studies show dose-dependent antineoplastic activity with influence on apoptosis, cell cycle, and cell signaling, increasing the cytotoxicity of the antineoplastic agent in cell lines of breast cancer treated with mitoxantrone and ascorbic acid.[12,13,14]

It has been proposed that the dietary supplementation of vitamin E, a lipid-soluble antioxidant, may reduce a woman's risk of developing breast cancer.[15,16] In animal models, vitamin E has decreased the incidence of carcinogen-induced mammary tumors. Intake and serum levels of vitamin E and their relation to breast cancer have been evaluated in epidemiologic studies.[17] Results of epidemiologic studies, however, have been conflicting. In this , we examine the evidence that is available pertaining to the relationship between vitamin E and breast cancer. Although epidemiologic study results have been inconsistent, further study of this nontoxic vitamin is warranted. Particular attention should be paid to the interactions of other antioxidants with vitamin E and to the duration and timing (pre- vs. postmenopausal) of vitamin E use in determining its preventive utility in breast cancer .[18,19]

CONCLUSION:

awareness with supplementation of natural antioxidant are beneficial to prevent the risk of breast cancer.

Abstract: The polycystic ovary syndrome (PCOS) is a mostly hyper androgenic disorder and is possibly the most common endocrinopathy of premenopausal women. The primary defect in polycystic ovary syndrome (PCOS) appears to be an exaggerated androgen synthesis (testosterone) (secretion by the ovaries and the adrenal glands) and hyperglycemia or insulin resistance. The objective of the study is to study the level of various Infertility hormones like FSH, LH, Progesterone, Estradiol, Testosterone, Insulin, HOMA-IR, Thyroid hormone (T3,T4,TSH)& Prolactin and in obese hyperglycemic and non-obese normoglycemic women of Polycystic ovarian syndrome(PCOD). This study includes total 500 female participants of age Group between 18-40 year of age**.** They were divided in to two group. Group 1(n=300) includes women having PCOD and Group 2(n=200) is control Group. Fasting Blood samples were obtained from all participants to measure Blood sugar, Lipid Profile, Testosterone, Progesterone, Estradiol FSH, LH, Insulin, HOMA-IR, Thyroid hormone(T3,T4,TSH) and Prolactin. History of PCOD women also had taken with Age, Menstrual cycle, hirsutism, acne, BMI, Waiste Hip ratio & Veg or Occasional Non-veg food diets. The Mean level of Fasting Blood sugar, S. cholesterol, S.Triglyceride, S. Insulin, S. Testosterone, S. Estradiol ,S.FSH ,and S.LH is found to be higher in both obese hyperglycemic & non-obese normoglycemic PCOD group (Except: S. Progesterone) as compared to control group and difference among them found to be statically significant. In PCOD women were also finds symptoms of oligomenorrhoea or anovulatory menstrual cycle, histustim with different F-G score, obesity in different ratio. From our study I would like to conclude that Obesity is a common finding in PCOS and aggravates many of its reproductive and metabolic features. The relationship between PCOS and obesity is complex, not well understood, and most likely involves interaction of genetic and environmental factors. Insulin resistance and weight gain are two contributing factors to PCOS. Insulin resistance typically causes the body to produce more insulin than normal (hyperinsulinemia). Higher levels of insulin can then cause ovaries to produce too much testosterone which can impair normal ovulation from occurring. Hyperandrogenism caused other secondary characteristics like Virilization, hirsutism (hairs on body), acne, obesity etc. These symptoms differ according to age of PCOD women, early age hyperandrogenism which further leads to metabolic syndrome with insulin resistance in later age.
Keywords: PCOD, Testosterone, Insuline, FSH, LH ,Prolactin, Progesterone, Estradiol, Thyroid hormone

INTRODUCTION

In polycystic ovary Syndrome (PCOS), increased androgen production results in high levels of luteinizing hormone (LH) and low levels of follicle-stimulating hormone (FSH), so that follicles are prevented from producing a mature egg. Without egg

production, the follicles swell with fluid and form into cysts. Every time an egg is trapped within the follicle, another cyst forms and the ovary swells, sometimes reaching the size of a grapefruit. Without ovulation, progesterone is no longer produced, whereas estrogen levels remain normal [1].

Factors that cause PCOS are insulin resistance & obesity, Genetic tendency, bad dietary habbits, weakened immune system, accumulation of toxins etc. In PCOS while diabetes mellitus and impaired glucose tolerance are easily diagnosed, the diagnosis of and concern for insulin resistance as a precursor disorder is underappreciated [2, 3].

Polycystic ovarian syndrome (PCOS) is a highly prevalent hormonal and metabolic disorder among reproductive aged women worldwide. Women with polycystic ovarian syndrome (PCOS) have widely varying phenotypes and seek medical care for differing reasons. In addition to concern for menstrual cycle function, ovulation, hirsutism and acne, many polycystic ovarian syndrome (PCOS) women have abnormal glucose metabolism.

MATERIAL & METHOD

This prospective study was conducted at Department of Biochemistry and Department of Obstetrics & Gynaecology, RNT Medical college and associated group of hospital, Udaipur, Rajasthan, India from June 2012-Dec 2013.

A total of 500 subjects of age group between 18-40 years belonging to both normal & polycystic ovary syndrome will be classified as:

Group-1:300 women with PCOD (Cases) of polycystic ovary disease will be taken.
Group-2:200 normal women will be taken as control for these parameters.

All PCOD women & controls were underwent a complete history and physical examination. Women with PCOD should be interviewed of their name, address, age, socio-economic status, and menstrual history, age of menarche, education level and family history of PCOD. All women were gone through gynaecological ultrasonography to determine their uterus and ovary condition.

Inclusion criteria

Women with PCOD are attending outdoor OPD of the hospital, first time diagnosed PCOD ,Diagnosed polycystic ovarian syndrome, age ranging from 18-40 years.Women with PCOD Willing to have physical examinations like Weight, Height, BMI, W/H ratio, Blood Pressure, Hirsutism, Acne, Dark patches, Virilization, Ultra sonography etc.

Polycystic ovary syndrome (PCOS) associated with Diabetes, obesity, cardiovascular disorders, Irregular menstrual disorder and anovulation, Hirsutism & Acne symptoms.

Exclusion criteria

Women with diagnosed adrenal hyperplasia, androgen secreting neoplasm, other pituitary (acromegaly) and adrenal disorders like Cushing syndrome, Virilizing adrenal or ovarian neoplasm**,** hyperProlactinemia and other infertility cause **,**Thyroid hormone related infertility, Women having history of smoking, taking alcohol or tobacco chewing**,** Any other type of gynaecologic complications except related with Polycystic ovary syndrome (PCOS) will be excluded from the study.

Fasting 10 ml venous blood samples were obtained from all participants and collected it in to fluoride and plain vaccutainer. A Uniq ID number was given to each sample to hidden the identity of participants. All samples were centrifugated at 3000 RPM at clinical biochemistry laboratory for a period of 10 minutes to obtain a Plasma and serum.

Blood Glucose (FBS) measured by GOD POD method and lipid profile (S.Cholesterol, Triglyceride, HDL, VLDL, LDL) measured by enzymatic colorimetric method from all samples.

Various Endocrinal Hormones like, Testosterone, LH, FSH, Estradiol, and Progesterone was measured by enzyme linked immune assay (ELISA) method based on electrochemilumnescence from all samples. Thyroid hormone and Prolactin was done only for case group (exlusion criteria).

After assessing all the values, Mean, Standard deviation of all subjects & parameters were analysed. Statistical analysis was performed with SPSS software. Comparison between cases and with control is done by independent student's t test. By using' values now P value is less than 0.05 (P value < 0.05), it is significant. Comparison of the categorical variables (among category comparison) was done by using Chi-Square test.

RESULTS & DISCUSSION

The present study has been conducted on 300 PCOD women attending in OPD of R.N.T. medical college & associated group of hospitals, Udaipur and Geetanjali medical college & hospital, Udaipur. The results have been compared with 200 age and matched health women. All subjects were taken in the age group of fertile age 18-40 years.

Clinical data of all groups were collected via a questionnaire supplemented with an interview & were subjected to:

1. Verbal consent has been taken from patient after explaining the aim of the study.
2. **History**
   - Marital status or single
   - Education - awareness about PCOD & its consequences.
   - Socioeconomic status- life style & diet (veg/non-veg/fastfood/junk food) behaviour of subjects
   - Menstrual history- to determine the period of cycle relate with PCOD symptoms
   - Past history-to know the no of children and any type of history of Diabetes, Hypertension
   - Family history- family history of poly cystic ovary disease.
   - Hirsutism- to examine for excessive male hair pattern in females.

3. **General Examination**
   - Blood pressure (systolic and Diastolic) – measured in semi recumbent position. Two blood pressure recording 4 hours apart have been obtained.
   - Body mass index (BMI) – equals to weight in kilograms devided by th square of the height in meters.

     BMI = (Weight in KG) / (Height in meters)^2

   - Abdominal examination – to determine any metabolic syndrome and inflammation.
   - Hirsuism examination (F-G score) - When evaluating a woman with hirsutism, the Ferriman–Gallwey (FG) score is a simple and commonly used method to quantify hair growth. This method evaluates nine androgen sensitive sites and grades them from 0 to 4. Scores between 8 and 15 are usually considered to be mild hirsutism, whereas scores greater than 25 indicate severe hirsutism. Some limitations of this scoring system include: (a) the variation in hair growth between different ethnic groups; (b) failure to account for regional hirsutism; and (c) the fact that many women may have treated their excessive hair growth with cosmetic measures, such as chemical depilatories, electrolysis, laser therapy, etc.

Ferriman-Gallway (F-G) score

This is the established and most prevalent system of measuring hirsutism. It was introduced in 1961. The scorecard of every body part analyzed began from 0 (zero terminal hairs) to 4 (massive terminal hair growth or frankly hirsute) and the numbers are added up to a maximum count of 36. The survey also suggested that hair production over the forearm and lower leg were less androgen receptive. This was an important finding since androgen is the main hormone that determines terminal hair production and its dysfunction is one of the main causes of hirsutism. Excluding the other nine body parts, 4.3% of patients evaluated registered a count of greater than 7. Hence, the experts conducting the study concluded that a score of 8 or more suggests hirsutism. Later there have been various modifications of the method. Some have been based on the analysis of hair production preferentially in the sideburn region, lower jaw, and upper neck, or perineal region and this has led to new measurement processes. Based on this score pattern and other clinical tests, hirsutism can be evaluated as mild, moderate or severe. DM Ferriman, JD Gallwey[4].

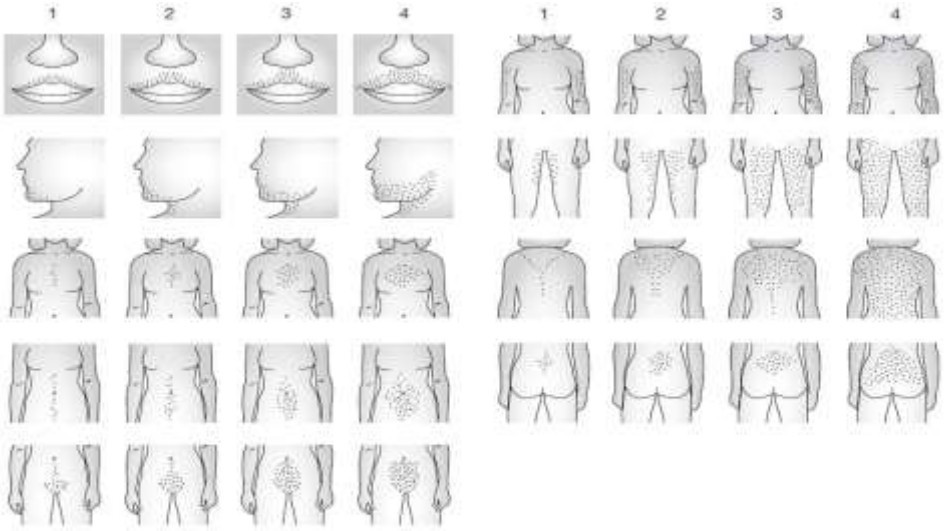

Figure 2 The modified Ferriman–Gallwey scoring system for hirsutism. Each of the nine body areas is rated from 0 (absence of terminal hairs) to 4 (extensive terminal hair growth) and the numbers in each area are added to obtain the total score. A score ≥6–8 generally defines hirsutism. Permission obtained from Humana Press © Azziz R *et al.* (2006) *Androgen Excess Disorders in Women: Polycystic Ovary Syndrome and Other Disorders*, edn 2. Totowa, NJ: Human Press.

Fig: The Modified Ferriman- Gallway scoring system [4]

Gynecological Ultrasonography

To determine condition of uterus and ovary whether normal or immature follicles as a form of poly cyst, their numbers, size and volume, specifically looking for small ovarian follicles. These are believed to be the result of disturbed ovarian function with failed ovulation, reflected by the infrequent or absent menstruation that is typical of the condition. In a normal menstrual cycle, one egg is released from a dominant follicle - essentially a cyst that bursts to release the egg. After ovulation the follicle remnant is transformed into a progesterone-producing corpus luteum, which shrinks and disappears after approximately 12–14 days.

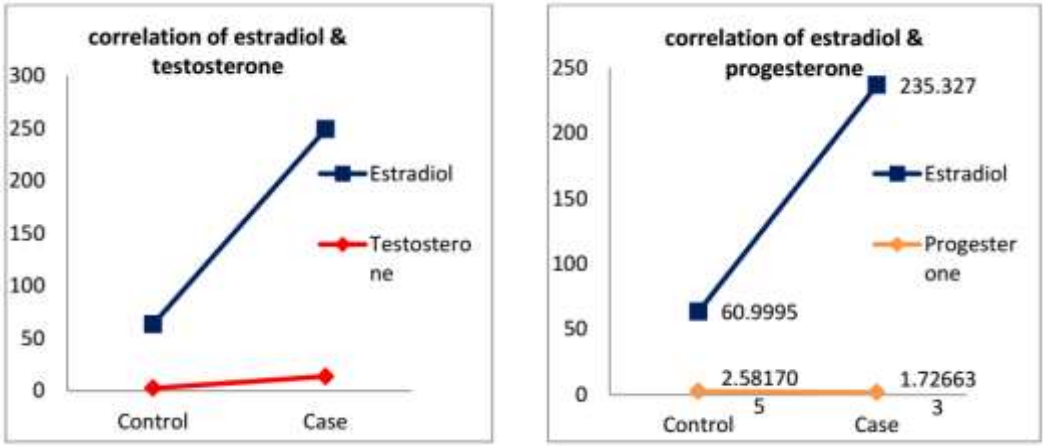
- Comparison of the fasting basal sugar (FBS) between the two groups shows that FBS is higher (mean value = 106.7 ± 19.49) in Cases group than Controls (mean value = 96.1 ± 17.0.(Table 8)
- Comparison of the Triglyceride (TG) between two groups shows that TG is higher (mean value = 160.6 ± 36.98) than Controls (mean value = 154.6 ± 23.42). Comparison of Total Cholesterol (TC) between two groups shows that TC is higher (mean value = 189.1 ± 45.47) in Cases than Controls.(Table 8)
- Comparison of the luteinizing hormone (LH) between two groups shows that LH is higher (mean value 147 ± 39) in Cases than Controls (mean value = 90.8 ± 43.6). (Table 9)
- Comparison of the follicular stimulating hormone (FSH) between two groups shows that FSH is higher (mean value 76.4 ± 45.6) in Cases than Controls (mean value = 22.2 ± 17.1). (Table 9)
- Testosterone is higher (mean value 13 ± 6.3) in Cases than Controls (mean value = 2.67 ± 1.4). (Table 9)

- Insulin hormone is higher (mean value 15.5 ± 6.2) in Cases than Controls (mean value = 7.4 ± 2.0). (Table 9)
- Estradiol is higher (mean value 235 ± 90.2) in Cases than Controls (mean value = 60.9 ± 19.6). (Table 9)
- Progesterone is higher (mean value 2.58 ± 3.1) in Controls than Cases (mean value = 1.72 ± 2.2). (Table 9)



Graph−4 & 5: correlation of estradiol & testosterone; correlation of Estradiol & progesterone

Comparison of various parameters in different group's categories among hyperglycemic/ diabetes mellitus cases

- In study there is comparison between vegetarian diets with fast food eaters and Nonvegetarian diets with fast food eaters in hyperglycaemic 74 cases out of 300 PCOD women cases. All parameters are higher in veg with FF eaters. Progesterone ng/ml mean values are 1.53 & 1.66 (lower in veg eaters) in hyperglyemic/DM women.(Table 11 & graph 1)
- In study there is comparison between Without Obesity &With Obesity in hyperglycaemic/DM 74 cases out of 300 PCOD women cases. All parameters are higher in Hyperglyemic /DM with obesity group. Progesterone ng/ml mean values are 1.74 & 1.32 (lower in Hyperglyemic /DM with obesity group) in women. (Table 12 & graph 2)**.**
- In study there is comparison among different groups of Oligomennrohea (O/M), O/M with Hirsutism & O/M without Hirsutism in 268 cases out of 300 PCOD women cases. All parameters are higher in O/M with Hirsutism group compare to O/M without Hirsutism group. Progesterone ng/ml mean values are 1.73, 1.64 & 1.9 (lower in O/M with Hirsutism group) in women (Table 13 & graph 3)**.**

Dunaif *et al*. said that in teenagers, abnormalities in glucose metabolism manifest prior to dyslipidemia, suggesting that assessment of glucose metabolism is even more important in younger women. DM is diagnosed by an 8 h fasting plasma glucose ≥ 126 mg/dL, 2 h glucose value ≥ 200 mg/dL after oral glucose tolerance test (OGTT) or random glucose ≥ 200 mg/dL with symptoms of DM confirmed by either fasting plasma glucose or OGTT. The prevalence of IGT in obese adolescents is surprisingly as high as 15%. It's interesting that despite all the research into PCOS, the exact relationship between the condition and weight gain (or loss) is unclear. But being overweight, and especially increased abdominal fat, seems to be a strong predictor of having other hormonal problems – such as raised male hormones and tendencies to having diabetes [5, 6].

Dahlgren E. *et al.* study, women with PCOS present a more atherogenic lipid profile with elevations of serum triglycerides (TG) and reductions of serum high density lipoprotein (HDL) cholesterol concentrations and are at a greater risk of cardiovascular diseases compared with age-matched control subjects. These clustering risk factors associated with PCOS emphasize the importance of studies to distinguish between metabolic and hormonal alterations which are related to PCOS or to obesity [7, 8].

Mckenna *et al.* Moghetti *et al***.** & Hammami *et al*., Most studies have shown hypersecretion of adrenal hormones in PCOS subjects compared with healthy women, but the mechanism of this hypersecretion is not well understood. Possible explanations include hypersensitivity of the adrenal gland to adrenocorticotrophic hormone (ACTH) stimulation, conjugated hypersecretion from the ovary and the adrenals, dysregulation of steroid synthesis enzymes

such as 11β-hydroxysteroid dehydrogenase (11β-HSD) and hyperstimulation of cytochrome *P*450c-17α activity in the adrenal glands as a result of hyperinsulinaemia in these patients[9-14,15].

Acien P *et al.* & Jayagopal V *et al.* studies show that obese (compared to lean) PCOS women tend to have a higher degree of IR. Correlation between hyperandrogenism and IR is significant in many studies but not as significant as the link between insulin abnormalities and obesity. PCOS women demonstrate greater variation in insulin parameters compared to controls, independent of weight. Some human data shows a high degree of correlation between hyperandrogenism and IR. The relationship between hyperandrogenism and IR seem to differ between PCOS and non-PCOS women [16-19].

Unfer *et al.* & Gluck *et al.* studies said that the ratio of LH (Luteinizing hormone) to FSH (Follicle stimulating hormone) is greater than 1:1 (sometimes more than 3:1), as tested on Day 3 of the menstrual cycle. The pattern is not very specific and was present in less than 50% in one study [20,21].

Knochenhaur ES *et al.* Asuncion M *et al.* studies show women presenting with menstrual dysfunction and hirsutism, 86% (and 68% of women with hirsutism but apparent eumenorrhea) had PCOS. Alternatively, in this populational study only 8% of patients with menstrual dysfunction alone (i.e. without hirsutism) had PCOS, raising questions regarding the high proportion of PCOS suggested affecting women with oligoovulatory infertility. Prevalence rate of reported menstrual dysfunction in our population was 22.8%. The incidence of oligomenorrhea (14.6%; 28 of 192) in the studied population may be overestimated because of the definition we used, i.e. less than 8 cycle/yr; this definition was also used in the recent study by Knochenhauer *et al*. H/A was confirmed in 6.77% of the examined women with oligomenorrhea or oligomenorrhea and hirsutism [21].

Hull MG *et al.* population, 74% of women with hirsutism were estimated to suffer from PCOS, and 76% (20.1 of 26.5) of women diagnosed with PCOS demonstrated hirsutism, consistent with our findings in studies of women seeking care for hirsutism [22].

The study demonstrates that there is a relationship between the degree of hormonal abnormality and the menstrual irregularities and hirsutism in women with PCOS suggesting that there may be a progressive nature to the syndrome.

One of the important etiologic factors in acne is an increase in sebaceous gland activity, which is androgen dependent. Acne is a common manifestation of hyperandrogenemia. Therefore, acne may not only cause cosmetic concern but may also be a sign of underlying disease. In females, the most common cause of hyperandrogenemia is polycystic ovary syndrome (PCOS).

CONCLUSION

Obesity is a common finding in PCOS and aggravates many of its reproductive and metabolic features. The relationship between PCOS and obesity is complex, not well understood, and most likely involves interaction of genetic and environmental factors. Insulin resistance and weight gain are two contributing factors to PCOS. Insulin resistance typically causes the body to produce more insulin than normal (hyperinsulinemia). Higher levels of insulin can then cause ovaries to produce too much testosterone which can impair normal ovulation from occurring and further leads to metabolic syndrome in PCOD women with symptoms of Hirsutism, Oligomennrohea and acne.

Abstract **Original Research Article**

Background: Polycystic ovary syndrome (PCOS) is a complex endocrine disorder affecting 5–10 % of women of reproductive age. It generally manifests with oligo/anovulatory cycles, hirsutism and polycystic ovaries, together with a considerable prevalence of insulin resistance. ***Objectives:*** The objective of the study is to establish correlation among testosterone, insulin, FSH, LH and lipid profile among the women with polycystic ovary syndrome (PCOS), in order to evaluate their diagnostic and prognostic significance**.** ***Methodology:*** This study includes total 300 female participants of age Group between 18-40 year of age**.** They were divided in to two groups. Group 1(n=150) includes women having PCOD and Group 2(n=150) is control Group. Fasting Blood samples were obtained from all participants to measure Blood sugar, Lipid Profile insulin, HOMA-IR, Testosteron, FSH, LH and Prolactine**.** ***Result:*** The Mean level of S.Testosteron, S.FSH, S.LH, S.Prolactine and HOMA-IR Fasting Blood sugar, S.cholesterol, S, and Triglyceride S.Insulin is found to be Lower Control Group as compared to PCOD group and difference among them found to be statically significant. ***Conclusion:*** From our study I would like to conclude that a PCOS, as a syndrome, has got multiple components including reproductive, metabolic and hormonal, with long-term health concerns that cross the life span. Moreover, PCOS patients have a higher risk of metabolic and cardiovascular diseases and their related morbidity, if compared to the general population.

Key words: PCOD, Insulin, HOMA-IR, Testosteron, FSH, LH, Prolactine.

INTRODUCTION

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in women and major cause of anovulatory infertility. PCOS patients can present a wide range of signs and symptoms, which make difficult the precise grading of the condition. Diagnosis of PCOS is currently based on the criteria of the ESRHE/ASRM Rotterdam consensus meeting in 2003 [1], which broadened the previous NIH classification of 1990 [2]. It based on at least two of the following features: oligo-anovulation, hyperandrogenism and polycystic ovaries by ultrasound [1]. In 2006, the Androgen Excess Society (AES) set up a committee of experts to review all the data published on PCOS for the purpose of simplifying diagnosis [3]. The AES criteria require clinical and/or biochemical hyperandrogenism simultaneously with oligo/anovulation and ultrasonographic evidence of polycystic ovaries.

There is increasing evidence suggesting that PCOS affects the whole life of a woman, can begin in utero in genetically predisposed subjects, it manifests clinically at puberty, continues during the reproductive years. It can also expose patients to increased risk of cardiovascular disease, hypertension, diabetes and other metabolic complications, especially after menopause [4]. During the fertile period it may cause anovulatory infertility and could be associated with increased prevalence of gestational complications, such as miscarriage, gestational diabetes and preeclampsia [5]. Early diagnosis is therefore crucial by enabling close follow-up and in an attempt to reduce the risk of such complications.

Therefore, the present investigations will be carried out to assess testosterone, LH, FSH & insulin hormones level, HOMA-IR level. Subsequently regular assessing of sugar glucose, lipid profile and differential diagnosis of prolactin (PRL) in clinical biochemistry laboratory is important to monitor & study the effect of these parameters among normal and polycystic ovary Syndrome (PCOS) women & its adverse consequences.

MATERIAL & METHOD

This prospective study was conducted at Department of Biochemistry and Department of

Obstetrics & Gynaecology, Geetanjali Medical College & Hospital, Udaipur, Rajasthan, India from June 2012-Dec 2013. A total of 300 subjects of age group between 18-40 years belonging to both normal & polycystic ovary syndrome will be classified as:

Group-1:150 women with PCOD (Cases) of polycystic ovary disease will be taken.
Group-2:150 normal women will be taken as control for these parameters.

All PCOD women & controls were underwent a complete history and physical examination. Women with PCOD should be interviewed of their name, address, age, socio-economic status, and menstrual history, age of menarche, education level and family history of PCOD. All women were gone through gynaecological ultrasonography to determine their uterus and ovaried condition.

Inclusion Criteria

Women with PCOD are attending outdoor OPD of the hospital, first time diagnosed PCOD, Diagnosed polycystic ovarian syndrome, age ranging from 18-40 years.

Women with PCOD Willing to have physical examinations like Weight, Height, BMI, W/H ratio, Blood Pressure, Hirsutism, Acne, Dark patches, Virilization, Ultra sonography etc.

Polycystic ovary syndrome (PCOS) associated with Diabetes,obesity, Cardiovascular disorders. Irregular menstrual disorder and anovulation, Hirsutism & Acne symptoms.

Exclusion Criteria

Women with diagnosed adrenal hyperplasia, androgen secreting neoplasm, other pituitary (acromegaly) and adrenal disorders like Cushing syndrome, Virilizing adrenal or ovarian neoplasm**,** hyperprolactinemia and other infertility cause, Thyroid hormone related infertility, Women having history of smoking, taking alcohol or tobacco chewing**,** Any other type of gynaecologic complications except related with Polycystic ovary syndrome (PCOS) will be excluded from the study.

Fasting 10 ml venous blood samples were obtained from all participants and collected it in to fluoride and plain vaccutainer. An Uniq ID number was given to each sample to hidden the identity of participants. All samples were centrifugated at 3000 RPM for a period of 10 minutes to obtain a Plasma and serum.

Blood Glucose (FBS) measured by GOD POD method and lipid profile (S. Cholesterol, Triglyceride, HDL, VLDL, LDL) measured by enzymatic colorimetric method from all samples.

Fasting Insulin level estimation was done by enzyme linked immune assay (ELISA) method based electrochemilumnescence and HOMA-IR will be estimated by calculation (fasting sugar×fasting insulin/22.5).

Various Endocrinal Hormones like testosterone, LH, FSH, Insulin and Prolactine was measured by enzyme linked immune assay (ELISA) method based on electrochemilumnescence from all samples.

After assessing all the values, Mean, Standard deviation of all subjects & parameters were analysed. Statistical analysis was performed with SPSS software. Comparison between cases and with control is done by independent student's t test. By using't' values now P value is less than 0.05 (P value < 0.05), it is significant. Comparison of the categorical variables (among category comparison) was done by using Chi-Square test.

RESULTS & DISCUSSION

Infertility, hirsutism, and oligomenorrhea were more common among the subjects with PCOS, but there was a considerable spontaneous restitution of cyclic regularity with time. Women with PCOS were more often hysterectomized and entered menopause later compared with referents. The hormone data show a typical profile for PCOS. Compared with referents women with PCOS showed marked increase in prevalence of central obesity, higher basal serum insulin concentrations, and a higher prevalence of diabetes mellitus and hypertension [65].

Table-1: Age wise distribution of participants

Group	Number(n)	Mean Age(Yr)
Group 1(PCOD)	150	26.30 ± 5.0
Group 2(Control)	150	24.50 ± 4.13

Table-2: Location wise distribution of participants

Location	Group 1(PCOD)	Group 2(Control)
Rural	57(38%)	36(36%)
Urban	93(62%)	64(64%)
Total	150(100%)	150(100%)

Table-3: Comparison of weight between case and control group

Group	Number(n)	Mean wt (kg)
Group 1(PCOD)	150	58.91 ± 5.24
Group 2(Control)	150	48.36 ± 5.8

Table-4: Comparison of waste hip(W/H) ratio between case and control group

Group	Number(n)	Mean W/H ratio
Group 1(PCOD)	150	0.84 ± 0.13
Group 2(Control)	150	0.79 ± 0.05

Table-5: Comparison of BMI between case and control group

Group	Number(n)	Mean BMI
Group 1(PCOD)	150	23.70 ± 2.73
Group 2(Control)	150	18.72 ± 2.41

Table-6: Comparison of Marital status between case and control group

Group	Number(n)	Married	single
Group 1(PCOD)	150	100(66.7%)	50(33.3%)
Group 2(Control)	150	59 (39%)	91(61%)

Table-7: Comparison based on menstrual cycle history between case and control group

			GROUP		Total
			Control	Cases	
M.H./CYCLE	<5	Count	0	11	11
		% within GROUP	0.0%	16.5%	3.66%
	5-9	Count	0	138	138
		% within GROUP	0.0%	92.3%	46%
	>=10	Count	150	1	151
		% within GROUP	100.0%	0.6%	50.33%
Total		Count	150	150	300
		% within GROUP	100.0%	100.0%	100.0%

Table-8: Showing valid Hirsutism status of Case group

TOTAL COUNTS	HIRSUTISM		NON HIRSUTISM	
	Counts	valid %	Counts	valid %
Cases (150)	80	53%	70	46%

Table-9: Comparison of various biochemical parameters between case and control group

parameter	Group	N	Mean SD	p-value
FBS(mg/dl)	Case	300	106.7 ± 19.4	<0.001
	Control	200	96.12 ± 17.03	
S.choletsterol(mg/dl)	Case	300	189.1 ± 45.47	<0.001
	Control	200	157.49 ± 23.80	
S.Triglyceride(mg/dl)	Case	300	160.69± 36.98	0.025
	Control	200	154.62 ± 23.42	
S.HDL(mg/dl)	Case	300	40.24 ± 6.30	0.006
	Control	200	38.66 ± 6.25	
S.LDL(mg/dl)	Case	300	116.95 ± 42	<0.001
	Control	200	87.98 ± 22.27	
S.VLDL(mg/dl)	Case	300	32.0± 7.32	0.032
	Control	200	30.84 ± 4.72	

Table-10: Comparison of level of various endocrinal hormonal statuses between case and control group

parameter	Group	N	Mean SD	p-value
S.LH(µIU/ml)	Case	150	147.12± 39.13	<0.001
	Control	150	90.86 ± 43.62

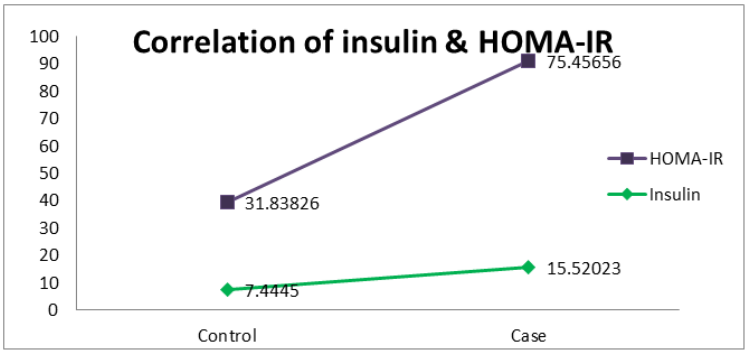
HOMA-IR	Case	150	75.45± 41.15	<0.001
	Control	150	31.83 ± 10.69	



Graph-1: Showing Correlation of insulin & HOMA-IR between case and control group

- Comparison of the fasting basal sugar (FBS) between the two groups shows that FBS is higher (mean value = 106.7 ± 19.49) in Cases group than Controls (mean value = 96.1 ± 17.0 (Table 9).
- Comparison of the Triglyceride (TG) between two groups shows that TG is higher (mean value = 160.6 ± 36.98) than Controls (mean value = 154.6 ± 23.42). Comparison of Total Cholesterol (TC) between two groups shows that TC is higher (mean value = 189.1 ± 45.47) in Cases than Controls (Table 9).
- Comparison of the luteinizing hormone (LH) between two groups shows that LH is higher (mean value 147 ± 39) in Cases than Controls (mean value = 90.8 ± 43.6) (Table 10).
- Comparison of the follicular stimulating hormone (FSH) between two groups shows that FSH is higher (mean value 76.4 ± 45.6) in Cases than Controls (mean value = 22.2 ± 17.1) (Table 10).
- Testosterone is higher (mean value 13 ± 6.3) in Cases than Controls (mean value = 2.67 ± 1.4) (Table 10).
- Insulin hormone is higher (mean value 15.5 ± 6.2) in Cases than Controls (mean value = 7.4 ± 2.0) (Table 10).
- HOMA-IR is higher (mean value 75 ± 41.1) in Cases than Controls (mean value = 31.8 ± 10.6) (Table 10).

Although the exact cause of PCOS is unknown, it is understood to be a multifactorial condition with a genetic component. Approximately 20–40% of first-degree female relatives of women with PCOS go on to develop PCOS themselves, compared to estimated 4–6% prevalence in the general population [6]. Many women with PCOS have female relatives with PCOS, even if it was never diagnosed as with type 2 diabetes, it is likely that numerous genes each make a small contribution to the etiology of PCOS; and recent genome-wide association studies have identified candidate genes [7-9]. Any underlying genetic predisposition is likely complicated by epigenetic and environmental factors such as an unhealthy diet and lack of physical activity.

Clinically, PCOS may manifest as a mild menstrual disorder or a severe disturbance of reproductive and metabolic functions [10]. Most visible signs are caused by excessive production of insulin or androgens. Hirsutism (excess hair growth on the face and body) is present in ~ 70% of women with PCOS and is considered to be a good marker for hyperandrogenism but should be evaluated biochemically.

CONCLUSION

From our study I would like to conclude that a PCOS, as a syndrome, has got multiple components including reproductive, metabolic and hormonal, with long-term health concerns that cross the life span. Moreover, PCOS patients have a higher risk of metabolic and cardiovascular diseases and their related morbidity, if compared to the general population.

Abstract:

Introduction:

According to Medical Council of India guidelines, regular periodical examinations shall be conducted throughout the course. The question of number of examinations is left to the institution. However it is seen that maximum medical institutes in India conduct at least two internal assessment (terminal) examinations but doesn't conduct part completion test.

Objectives:

To observe the effectiveness of conducting part completion tests for improvement of academic performance in terminal examination and also to take feedback from faculties and students.

Methods:

Permission was taken from Institutional Ethical Committee. Five part completion test and one terminal examination were conducted. 122 First MBBS students were enrolled. Groups were divided according to number of students appeared in part completion tests and terminal examination. Feedback was taken using Likert's Scale.

Results:

There were zero students in group I, 6 in group II, 28 in Group III, 69 in group IV and 19 in group V. There was increase in percentage of marks from group II to III (8%), group III to IV (15%) and group IV to V (24%). There was significant difference in marks among different group (F= 3.76; p <

0.01). Comparison of average marks shows highly significant value (Coefficient of Correlation, r = 0.965916).

Conclusion:

Those students who have given more number of part completion tests scored well in terminal examination.Faculties and students have agreed that these part completion tests are necessary, will give better outcome on performance of terminal examination, and part completion test should be incorporated in curriculum.

Introduction:

Biochemistry is one of the basic subjects of medical sciences. A well designed curriculum, teaching and learning activities and assessment methods are essential for better academic performance of the students[1- 3]. Medical Council of India (MCI) has placed a lot of emphasis on internal assessment examination. According to MCI guidelines, internal assessment shall be on day to day assessment including assignments, preparation for seminar, clinical case presentation, preparation of clinical case for discussion, clinical case study/problem solving exercise, participation in project for health care in the community, proficiency in carrying out a practical or a skill in small

research project, multiple choice questions after completion of a system/teaching etc. Regular periodical examinations shall be conducted throughout the course. The question of number of examinations is left to the institution[4]. There shall be no less than two internal assessment examination in each non clinical department[5]. However it is seen that maximum medical institute in India conduct at least two internal assessment examinations (terminal or semester examination) but doesn't conduct part completion test.

Part completion test is a type of formative assessment. It is conducted upon completion of small portion of syllabus. The terminal examination is conducted at completion of every term and is a mirror image of summative examination and is considered as a rehearsal for that.

Aims and Objectives:

Aim:

To observe the effectiveness of conducting part completion tests in Biochemistry for improvement of academic performance in terminal examination.

Objectives:

To see the difference in performance of students who have given one or more part completion test with the result of their terminal examination.

To take perception of the students that whether conducting part completion tests has benefited them to perform well in terminal examination and to get feedback from faculties of Biochemistry department regarding the feasibility of conducting part completion tests.

Methodology:

This study was carried out at Department of Biochemistry, Ananta Institute of Medical Sciences and Research Centre, Rajsamand, Rajasthan State. The project was of six months commencing from the month of October 2018 and was a prospective longitudinal study. This project was approved by Institutional Ethical Committee. A total of 122 students of M.B.B.S. Batch: 2018 - 2019 was included in this study after obtaining their voluntary written informed consent. Twenty Eight (28) students were not allowed to appear in the terminal examination due to shortage of attendance. Eight faculties of biochemistry department were also included in this study. The study included 5 part completion tests of 20 marks each and one terminal examination of 50 marks

(Written pattern). The pattern of part completion test was kept similar to that of terminal examination.

Inclusion Criteria:

Those students who have appeared for terminal examination.

Exclusion Criteria:

Students who have not appeared in terminal examination.

Students who have not appeared in at least one part completion test examination.

Hence the study comprised of following groups for comparative analysis:

Group I: Students appeared in one part completion test and terminal examination. (n = 0)

Group II: Students appeared in two part completion tests and terminal examination. (n = 6)

Group III: Students appeared in three part completion tests and terminal examination. (n = 28)

Group IV: Students appeared in four part completion tests and terminal examination. (n = 69)

Group V: Students appeared in five part completion tests and terminal examination. (n = 19)

Feedback from faculties of Biochemistry department regarding feasibility of part completion test was taken. Faculty has to answer the questions for rating from 1 to 5 (1 = minimum and 5 = maximum: Likert Scale). Average Score and Interpretation was drawn after the feedback.

Q.1. Is all these part completion tests necessary ?

Q.2. Will be there any better outcome of these part completion tests in terms of performance in terminal examination.

Q.3. Would you think these part completion tests disturbing day to day teaching activities of students

Q.4. Would you think that these part completion tests are having impact on attendance of student

Q.5. Would you think this part completion tests to be incorporated as a part of curriculum.

Perception in terms of feedback from student of M.B.B.S. Batch 2018 - 19 regarding part completion tests was taken. Students have to answer the questions for rating from 1 to 5 (1 = minimum and 5 = maximum: Likert Scale). Average Score and Interpretation was drawn after the perception.

Q.1. Do you think that these part completion tests necessary?

Q.2. Will is there any better outcome of these part completion tests in terms of your performance in terminal examination.

Q.3. Would you think these part completion test disturbing your day to day teaching activities

Q.4. Would you think that these part completion tests are having impact on your attendance

Q.5. Would you think this part completion tests to be incorporated as a part of curriculum.

Statistical Analysis:

Data was analysed in terms of either increase or decrease in percentage of marks among the groups. Statistical analysis was done on SPSS statistical software. $P < 0.05$ was considered statistically significant. Coefficient correlation and ANOVA was applied to see the statistical difference among groups.

Results:

A total of 122 students out of 150 were enrolled in this study after applying inclusion and exclusion criteria. There were zero students in group I, 6 in group II, 28 in Group III, 69 in group IV and 19 in group V. There was increase in percentage of marks from group II to III (8%), group III to IV (15%) and group IV to V (24%). (Table 1) By applying ANOVA, it was seen that there was significant difference in marks among different groups ($F= 3.76$; $p < 0.01$), although there was no significant difference between groups. (Table 1) Comparison of average marks between marks of part completion test and terminal examination shows highly significant value (Coefficient of Correlation, $r = 0.965916$) (Table 1). Hence we can see that those students who have given more number of part completion tests scored well in terminal examination.

Table 1 : Comparison between groups for terminal examination marks.

	Group II (n=6)	Group III (n=28)	Group IV (n=69)	Group V (n=19)
Increase in percentage of marks	--	8 %	15 %	24 %
ANOVA	F= 3.76; p < 0.01 (statistically significant among groups) Average marks of different groups in terminal examination			
Coefficient of Correlation	r = 0.965916 (highly significant) Comparison of average marks of Part Completion test and Terminal Examination			

P < 0.05 was considered statistically significant. Note: Results are not generalized

Figure No.1 shows perception from students for part completion test. Students have agreed that these part completion tests are necessary and will give better outcome on performance of terminal examination and also will have impact on attendance. They also agree that part completion test should be incorporated in curriculum. Students also agreed that these part completion tests are disturbing day to day teaching activity.

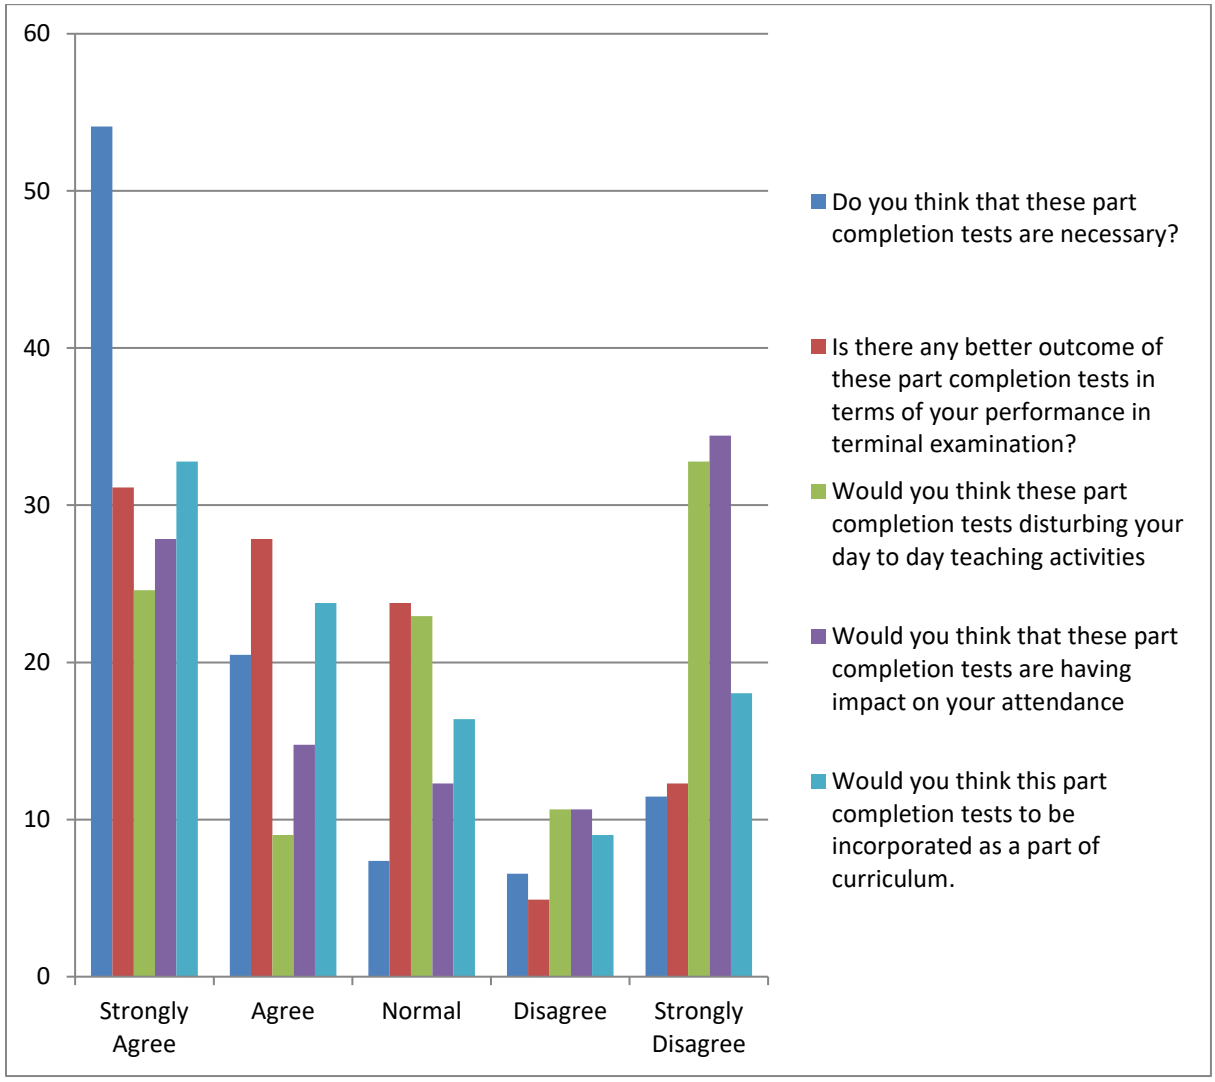

Figure No. 1

Perception from Students (n = 122) by Likert's Scale

Figure No. 2 shows perception from faculties for part completion test. Faculties have agreed that these part completion tests are necessary and will give better outcome on performance of terminal examination and also will have impact on attendance. They also agree that part completion test should be incorporated in curriculum. However faculties disagreed that these part completion tests are disturbing day to day teaching activity.

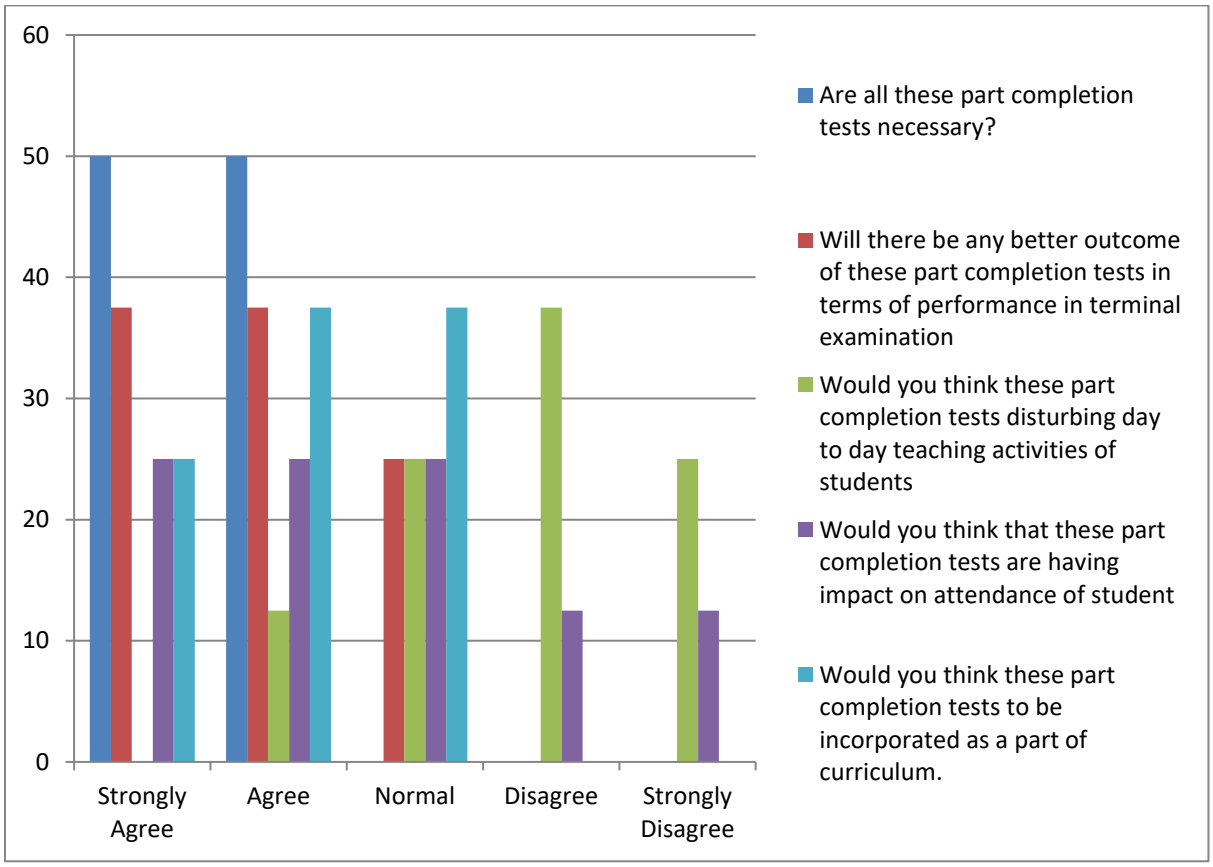

Figure No. 2

Feedback from faculties (n = 8) by Likert's Scale[6]

Discussion:

Assessment is driving force for student in learning. Continuous assessment plays a vital role in influencing the summative exam performance. Santra et al[7] found a strong correlation between internal assessment marks and professional exam marks. Karpicke and Roediger[8] showed that repeated testing produced a large positive effect on long term retention, while repeated studying has

no effect. It is universally accepted fact that students are under severe stress and anxiety during professional exams as compared to day to day exams. Studies have proven that exam anxiety interfere with academic performance[9].

So under these all observations, it was interesting to know whether conducting part completion tests will have better outcome in form of performance in terminal examinations. Hence in order to improve the internal assessment marks, we have conducted this study to see the effect of written test in day to day assessment, presuming that this practice might help students to perform better in terminal exams and henceforth in summative exams as well.

In our study, we have found that, those students who have given more number of part completion tests scored well in terminal examination as compared to those who have given less.

Faculties and students have agreed that these part completion tests are necessary and will give better outcome on performance of terminal examination and also will have impact on attendance. They also agree that part completion test should be incorporated in curriculum. However students agreed and faculties do not agree that these part completion tests are disturbing day to day teaching activity.

Abstract **Original Research Article**

Background: Polycystic ovary syndrome (PCOS) is a complex endocrine disorder affecting 5–10 % of women of reproductive age. It generally manifests with oligo/anovulatory cycles, hirsutism and polycystic ovaries, together with a considerable prevalence of insulin resistance. ***Objectives:*** The objective of the study is to establish correlation among testosterone, insulin, FSH, LH and lipid profile among the women with polycystic ovary syndrome (PCOS), in order to evaluate their diagnostic and prognostic significance**.** ***Methodology:*** This study includes total 300 female participants of age Group between 18-40 year of age**.** They were divided in to two groups. Group 1(n=150) includes women having PCOD and Group 2(n=150) is control Group. Fasting Blood samples were obtained from all participants to measure Blood sugar, Lipid Profile insulin, HOMA-IR, Testosteron, FSH, LH and Prolactine**.** ***Result:*** The Mean level of S.Testosteron, S.FSH, S.LH, S.Prolactine and HOMA-IR Fasting Blood sugar, S.cholesterol, S, and Triglyceride S.Insulin is found to be Lower Control Group as compared to PCOD group and difference among them found to be statically significant. ***Conclusion:*** From our study I would like to conclude that a PCOS, as a syndrome, has got multiple components including reproductive, metabolic and hormonal, with long-term health concerns that cross the life span. Moreover, PCOS patients have a higher risk of metabolic and cardiovascular diseases and their related morbidity, if compared to the general population.

Key words: PCOD, Insulin, HOMA-IR, Testosteron, FSH, LH, Prolactine.

INTRODUCTION

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in women and major cause of anovulatory infertility. PCOS patients can present a wide range of signs and symptoms, which make difficult the precise grading of the condition. Diagnosis of PCOS is currently based on the criteria of the ESRHE/ASRM Rotterdam consensus meeting in 2003 [1], which broadened the previous NIH classification of 1990 [2]. It based on at least two of the following features: oligo-anovulation, hyperandrogenism and polycystic ovaries by ultrasound [1]. In 2006, the Androgen Excess Society (AES) set up a committee of experts to review all the data published on PCOS for the purpose of simplifying diagnosis [3]. The AES criteria require clinical and/or biochemical hyperandrogenism simultaneously with oligo/anovulation and ultrasonographic evidence of polycystic ovaries.

There is increasing evidence suggesting that PCOS affects the whole life of a woman, can begin in utero in genetically predisposed subjects, it manifests clinically at puberty, continues during the reproductive years. It can also expose patients to increased risk of cardiovascular disease, hypertension, diabetes and other metabolic complications, especially after menopause [4]. During the fertile period it may cause anovulatory infertility and could be associated with increased prevalence of gestational complications, such as miscarriage, gestational diabetes and preeclampsia [5]. Early diagnosis is therefore crucial by enabling close follow-up and in an attempt to reduce the risk of such complications.

Therefore, the present investigations will be carried out to assess testosterone, LH, FSH & insulin hormones level, HOMA-IR level. Subsequently regular assessing of sugar glucose, lipid profile and differential diagnosis of prolactin (PRL) in clinical biochemistry laboratory is important to monitor & study the effect of these parameters among normal and polycystic ovary Syndrome (PCOS) women & its adverse consequences.

MATERIAL & METHOD

This prospective study was conducted at Department of Biochemistry and Department of

Obstetrics & Gynaecology, Geetanjali Medical College & Hospital, Udaipur, Rajasthan, India from June 2012-Dec 2013. A total of 300 subjects of age group between 18-40 years belonging to both normal & polycystic ovary syndrome will be classified as:

Group-1:150 women with PCOD (Cases) of polycystic ovary disease will be taken.
Group-2:150 normal women will be taken as control for these parameters.

All PCOD women & controls were underwent a complete history and physical examination. Women with PCOD should be interviewed of their name, address, age, socio-economic status, and menstrual history, age of menarche, education level and family history of PCOD. All women were gone through gynaecological ultrasonography to determine their uterus and ovaried condition.

Inclusion Criteria

Women with PCOD are attending outdoor OPD of the hospital, first time diagnosed PCOD, Diagnosed polycystic ovarian syndrome, age ranging from 18-40 years.

Women with PCOD Willing to have physical examinations like Weight, Height, BMI, W/H ratio, Blood Pressure, Hirsutism, Acne, Dark patches, Virilization, Ultra sonography etc.

Polycystic ovary syndrome (PCOS) associated with Diabetes,obesity, Cardiovascular disorders. Irregular menstrual disorder and anovulation, Hirsutism & Acne symptoms.

Exclusion Criteria

Women with diagnosed adrenal hyperplasia, androgen secreting neoplasm, other pituitary (acromegaly) and adrenal disorders like Cushing syndrome, Virilizing adrenal or ovarian neoplasm**,** hyperprolactinemia and other infertility cause, Thyroid hormone related infertility, Women having history of smoking, taking alcohol or tobacco chewing**,** Any other type of gynaecologic complications except related with Polycystic ovary syndrome (PCOS) will be excluded from the study.

Fasting 10 ml venous blood samples were obtained from all participants and collected it in to fluoride and plain vaccutainer. An Uniq ID number was given to each sample to hidden the identity of participants. All samples were centrifugated at 3000 RPM for a period of 10 minutes to obtain a Plasma and serum.

Blood Glucose (FBS) measured by GOD POD method and lipid profile (S. Cholesterol, Triglyceride, HDL, VLDL, LDL) measured by enzymatic colorimetric method from all samples.

Fasting Insulin level estimation was done by enzyme linked immune assay (ELISA) method based electrochemilumnescence and HOMA-IR will be estimated by calculation (fasting sugar×fasting insulin/22.5).

Various Endocrinal Hormones like testosterone, LH, FSH, Insulin and Prolactine was measured by enzyme linked immune assay (ELISA) method based on electrochemilumnescence from all samples.

After assessing all the values, Mean, Standard deviation of all subjects & parameters were analysed. Statistical analysis was performed with SPSS software. Comparison between cases and with control is done by independent student's t test. By using't' values now P value is less than 0.05 (P value < 0.05), it is significant. Comparison of the categorical variables (among category comparison) was done by using Chi-Square test.

RESULTS & DISCUSSION

Infertility, hirsutism, and oligomenorrhea were more common among the subjects with PCOS, but there was a considerable spontaneous restitution of cyclic regularity with time. Women with PCOS were more often hysterectomized and entered menopause later compared with referents. The hormone data show a typical profile for PCOS. Compared with referents women with PCOS showed marked increase in prevalence of central obesity, higher basal serum insulin concentrations, and a higher prevalence of diabetes mellitus and hypertension [65].

Table-1: Age wise distribution of participants

Group	Number(n)	Mean Age(Yr)
Group 1(PCOD)	150	26.30 ± 5.0
Group 2(Control)	150	24.50 ± 4.13

Table-2: Location wise distribution of participants

Location	Group 1(PCOD)	Group 2(Control)
Rural	57(38%)	36(36%)
Urban	93(62%)	64(64%)
Total	150(100%)	150(100%)

Table-3: Comparison of weight between case and control group

Group	Number(n)	Mean wt (kg)
Group 1(PCOD)	150	58.91 ± 5.24
Group 2(Control)	150	48.36 ± 5.8

Table-4: Comparison of waste hip(W/H) ratio between case and control group

Group	Number(n)	Mean W/H ratio
Group 1(PCOD)	150	0.84 ± 0.13
Group 2(Control)	150	0.79 ± 0.05

Table-5: Comparison of BMI between case and control group

Group	Number(n)	Mean BMI
Group 1(PCOD)	150	23.70 ± 2.73
Group 2(Control)	150	18.72 ± 2.41

Table-6: Comparison of Marital status between case and control group

Group	Number(n)	Married	single
Group 1(PCOD)	150	100(66.7%)	50(33.3%)
Group 2(Control)	150	59 (39%)	91(61%)

Table-7: Comparison based on menstrual cycle history between case and control group

			GROUP		Total
			Control	Cases	
M.H./CYCLE	<5	Count	0	11	11
		% within GROUP	0.0%	16.5%	3.66%
	5-9	Count	0	138	138
		% within GROUP	0.0%	92.3%	46%

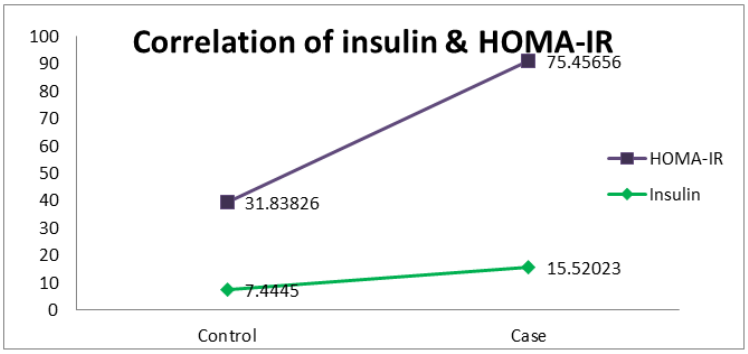
	Control	200	87.98 ± 22.27	
S.VLDL(mg/dl)	Case	300	32.0± 7.32	0.032
	Control	200	30.84 ± 4.72	

Table-10: Comparison of level of various endocrinal hormonal statuses between case and control group

parameter	Group	N	Mean SD	p-value
S.LH(µIU/ml)	Case	150	147.12± 39.13	<0.001
	Control	150	90.86 ± 43.62	
S.FSH(µIU/ml)	Case	150	76.42 ± 45.67	<0.001
	Control	150	22.22 ± 17.11	
S. Testosteron(ng/ml)	Case	150	13.82 ± 6.38	<0.001
	Control	150	2.67 ± 1.48	
S. Insulin(U/ML)	Case	150	15.52 ± 6.29	<0.001
	Control	150	7.44 ± 2.04	
HOMA-IR	Case	150	75.45± 41.15	<0.001
	Control	150	31.83 ± 10.69	



Graph-1: Showing Correlation of insulin & HOMA-IR between case and control group

- Comparison of the fasting basal sugar (FBS) between the two groups shows that FBS is higher (mean value = 106.7 ± 19.49) in Cases group than Controls (mean value = 96.1 ± 17.0 (Table 9).
- Comparison of the Triglyceride (TG) between two groups shows that TG is higher (mean value = 160.6 ± 36.98) than Controls (mean value = 154.6 ± 23.42). Comparison of Total Cholesterol (TC) between two groups shows that TC is higher (mean value = 189.1 ± 45.47) in Cases than Controls (Table 9).
- Comparison of the luteinizing hormone (LH) between two groups shows that LH is higher (mean value 147 ± 39) in Cases than Controls (mean value = 90.8 ± 43.6) (Table 10).
- Comparison of the follicular stimulating hormone (FSH) between two groups shows that FSH is higher (mean value 76.4 ± 45.6) in Cases than Controls (mean value = 22.2 ± 17.1) (Table 10).
- Testosterone is higher (mean value 13 ± 6.3) in Cases than Controls (mean value = 2.67 ± 1.4) (Table 10).
- Insulin hormone is higher (mean value 15.5 ± 6.2) in Cases than Controls (mean value = 7.4 ± 2.0) (Table 10).
- HOMA-IR is higher (mean value 75 ± 41.1) in Cases than Controls (mean value = 31.8 ± 10.6) (Table 10).

Although the exact cause of PCOS is unknown, it is understood to be a multifactorial condition with a genetic component. Approximately 20–40% of first-degree female relatives of women with PCOS go on to develop PCOS themselves, compared to estimated 4–6% prevalence in the general population [6]. Many women with PCOS have female relatives with PCOS, even if it was never diagnosed as with type 2 diabetes, it is likely that numerous genes each make a small contribution to the etiology of PCOS; and recent genome-wide association studies have identified candidate genes [7-9]. Any underlying genetic predisposition is likely complicated by epigenetic and environmental factors such as an unhealthy diet and lack of physical activity.

Clinically, PCOS may manifest as a mild menstrual disorder or a severe disturbance of reproductive and metabolic functions [10]. Most visible signs are caused by excessive production of insulin or androgens. Hirsutism (excess hair growth on the face and body) is present in ~ 70% of women with PCOS and is considered to be a good marker for hyperandrogenism but should be evaluated biochemically.

CONCLUSION

From our study I would like to conclude that a PCOS, as a syndrome, has got multiple components including reproductive, metabolic and hormonal, with long-term health concerns that cross the life span. Moreover, PCOS patients have a higher risk of metabolic and cardiovascular diseases and their related morbidity, if compared to the general population.

ABSTRACT

Background: Scheduled Tribe people being about 8% of the total population in India and 13 per cent of total population of Rajasthan form a distinct group compared to other populations and is the most underprivileged section of society. The people especially women and adolescent girls are at a higher risk of under-nutrition and micronutrient deficiency leading to iron deficiency anemia. A depleted iron status may largely affect the thyroid function of tribal females and this still remains unexplored. **Materials and Methods**: The present study conducted in adolescent school going girls of local tribal community. Their blood samples were tested for various parameters like hemoglobin, serum iron, iron binding capacity and Throtropin stimulating hormone (TSH). **Results**: The investigation hereby reports anemia in 79.5% of girls. Among anaemic 47.05% were mildly anaemic and 22.5% were moderately anaemic and 9.8% of the total girls were found to suffer from severe anemia. A significant reduction in iron status confirmed anemic conditions due to iron deficiency. Significantly increased TSH levels were observed in moderate and severely anemic girls.**Conclusion:** A reduced iron status may result in clinical or subclinical hypothyroidism in adolescent girls.

Keywords: Anemia, Scheduled tribes, adolescent girls, hypothyroidism

INTRODUCTION:

The prevalence of anaemia in developing countries is relatively high ranging from 33 percent to 75 percent **(1)**. In India, anemia is classified as a major public health problem as 52% of non pregnant women of reproductive age are estimated to suffer from this condition **(2)**. Various studies conducted in India further confirm the high prevalence of anemia among adolescent girls and women due to micronutrient deficiency and anaemia trends remain strongly correlated with iron-deficiency **(3-6)**. The low dietary intake of iron and folic acid coupled with poor bio-availability of iron is the major factor responsible for very high prevalence of anemia in the country **(7)**.

Scheduled Tribe people constitute about 8% of the total population in India and 13 per cent of total population of Rajasthan, with varying proportions in different states. They live in unique physical, socio-economic and cultural environment, isolated from general population. They form a distinct group compared to other populations and is the most underprivileged section of society **(8)**. The tribal population is at a higher risk of under-nutrition,

because of the socio-cultural, socio-economic and environmental factors influencing the food intake and health seeking behaviour. Iron-deficiency anemia is widespread yet the most neglected micronutrient deficiency disorder among children, adolescence girls, and pregnant women of scheduled tribes **(9-11)**.

Many studies suggest that hypothyroidism should be suspected in patients who have anemia with an unknown aetiology. It has been shown in various studies that for adequate functioning of thyroid hormone various minerals and trace elements are considered to be important. Iron is one of such element that is required in metabolism of thyroid hormone **(12)** as it acts as a co-factor in catalyzing the activity of some important biological enzymes including thyroid peroxidase TPO **(13)**. TPO, a membrane bound enzyme is reported to be responsible for the oxidation of iodide and binding of iodine to tyrosin residue of thyroglobulin **(14)**. A lower iron status may decrease the efficiency of TPO and thereby affect the overall thyroid hormone metabolism **(15)**.

The female population of tribal community is likely at increased risk for iron deficiency, since there is a high prevalence of anemia. The effects of depletion of iron status may largely affect the thyroid function of tribal females and this still remains unexplored. The main goal of this study is to better understand the relationship between iron status, as measured by hemoglobin, serum Iron, total iron binding capacity (TIBC) and thyrotropin stimulating hormone in adolescent females attending schools. Thus the study was conducted to find out the proportion of hypothyroidism in both anemic and non-anemic school going girls of age group 12-18 years of tribal area of Southern Rajasthan specifically Udaipur. Our study aims to determine the association between iron deficiency anemia and hypothyroidism, if any.

MATERIALS AND METHODS:

Study area : Unfortunately, prevalence of anemia and its effect on thyroid function in adolescent school going girls of tribal community has been the least explored area of research, particularly in Southern Rajasthan. This community-based study was undertaken to assess the iron deficiency anemia and its correlation with hypothyroidism in adolescent school going girls of local tribal community residing in Udaipur district.

Informed oral consent was obtained from the children's teachers and families. Ethical approval for the study was obtained from the Institutional Ethical Committees of Geetanjali University, Udaipur. In the first step, subjects who fulfilled all of the inclusion criteria were chosen for the study. A total of 102 girls of tribal community (with or without iron-deficiency) were enrolled from 8th standard to 12th standard.

Inclusion criteria: Adolescent school girls, aged 12-18years, unmarried, not on hormonal therapy, no history of anemia or hypothyroidism, with no history of any autoimmune disease, not taking any vitamin or iron supplementation were included.

Exclusion criteria: Male participants, females above 18 years, married,, females on hormonal therapy, or on vitamin or iron supplementation, with a history of anemia, hypothyroidism or any other chronic or autoimmune disease were excluded.

Biochemical analyses: 5 ml fasting venous blood samples were drawn from the arm. Blood was collected in two different test tubes; 2 ml were placed in the EDTA tube for measurement of hemoglobin and 3 ml in another tube for determination of serum iron, TIBC, thyrotropin stimulating hormone (TSH). Anemia was diagnosed according to WHO guidelines **(16)** (Demaeyer, 1985) (Table 1). The quantitative measurement of serum iron, and total iron binding capacity (TIBC) was performed. Transferrin saturation was calculated as follows: (serum iron/TIBC) ×100. The quantitative measurement of thyroid stimulating hormone (TSH) was done using chemiluminescence immunoassay.

Data analysis: The master chart was prepared by using the EXCEL 2007 software. Mean values and standard deviations were presented. The data which were obtained were analyzed statistically by using online student t-test calculator. P value less than 0.005 was considered as a

RESULTS:

1. Prevalence of anaemia according to the severity of anaemia:

In the present study, of the 102 adolescent girls, 21 (20.5 %) girls were having normal Hb (>12gms/dl) and 81 (79.5%) were anaemic. Among anaemic 48 (47.05%), were mild anaemic and 23 (22.5%) of the girls were moderately anaemic having mean Hb. 10 (9.8%) of the total girls were found to suffer from severe anemia Table 2.

2. Iron status of anemic and non anemic girls

There was significant reduction in serum iron level in moderately and severely anemic girls as compared to that of non anemic girls. No significant correlation was observed in mildly anemic girls. Further, a signicant increase in all anemic females was observed as compared to girls having normal hemoglobin levels. Transnerrin saturation percentage less than 16% depicts iron deficiency, moderately and severely anemic girls were found to have severe iron deficiency (Table 3).

3. Correlation of iron deficiency and TSH

Significantly increased TSH levels were observed in moderate and severely anemic girls. There was not significant increase in mild anemic girls (Table 3).

DISCUSSION

This is the first study report prevalence of anemia and its correlation with thyroid dysfunction in adolescent school going girls of local tribal community of Udaipur. In females, adolescence marks the beginning of the menstrual cycle or reproduction. Adolescents gain 30% of their adult weight and more than 20% of their adult height between 10-19 years, which is mentioned as growth spurt **(17)**. Adolescent girls are at a high risk for anaemia as there is increased iron requirement because of growth and menstrual loss. Malnutrition and inadequate nutrition during adolescence may result in serious consequences throughout the reproductive years of life and beyond **(18)**.

The data from the District Nutrition Project (Indian Council of Medical Research) in 16 districts of 11 states of India including Rajasthan, on the prevalence of anemia in non-pregnant adolescent girls (11-18 years) in year 2002, also demonstrated anemia as high as 90.1% out of which 7.1% of the girls were reported to suffer from severe anemia i.e. Hemoglobin <7 g/dl **(19)**. It has been further reported by Indian Institute for Population Sciences and Ministry of Health and Family Welfare in 2006, that in India, 98 percent of adolescent girls have any anemia. Twenty two percent of them are mildly anemic, 49 percent are moderately anemic and 27 percent are suffering from severe anemia. Severely anemic adolescent girls are highest among Scheduled Tribes as compared to other castes vide DLHS, 2002-2004 **(20)**.

According to Vyas and Choudhary (2005) 93.7 per cent school children were reported to suffer from different forms of anaemia confirming high prevalence of anaemia in the tribal school children of Udaipur region **(8)**. Our study conducted during 2014-15, in adolescent school going girls of local tribal community hereby reports anemias, in the studied group of girls upto 79.5%. 47.05% of girls were having mild anemia, 22.5% were moderately anemic and 9.8% were severely anemic. A very high prevalence of anaemia in our study could be attributed to lower socio-economic status and nutritional deficiencies found in adolescent girls of tribal population, as similar results were reported in adolescent girls of certain slum areas **(21)**. Respective transfrrin saturation percentages were also observed below the normal levels depicting lower iron status.

Studies have shown that anemia is an indicator of poor nutrition and poor health, with major consequences on the human health as well as on the social and economic development.

According to the WHO, if the prevalence of anemia at the community levels is more than 40%, it should be considered as a problem of high magnitude **(22)** The present study thus brings out the fact that the problem of anemia is related to a wider population than the traditionally considered groups of the non pregnant adolescent females. Our study further confirmed that the anemia in studied population is

due to reduction in iron status. Significant changes in TIBC and Serum iron confirmed that anemic condition in these females is due to iron deficiency.

None of studies have yet reported the relationship between anemia and thyroid dysfunction in adolescent girls in India till date. Though such kind of relationship has been demonstrated by Eftekhari and coworkers in iron-deficient adolescent Iranian girls **(23-24)**. Normal thyroid status is dependent on the presence of many trace elements e.g., iron, iodine, selenium, and zinc for both the synthesis and metabolism of thyroid hormones **(12, 25)**. Iron is very intricately connected to thyroid hormone metabolism. Therefore, estimation of serum iron and total iron binding is of great significance in thyroid dysfunction. Our study clearly addressed the association of iron status with hypothyroidism by estimating Hb level, serum iron, TIBC, trasferrin saturation and serum TSH levels. The estimation of serum TSH the is single best screening parameter for hypothyroidism therefore only serum TSH was measured which is increased in primary hypothyroidism **(26)**.

Our study demonstrates that TSH levels were significantly higher in all the girls of tribal community having moderate and severe anemia as compared to non anemic girls. Our results are in accordance with other studies which demonstrated increased levels of TSH and low levels of thyroid hormones in associated with reduced body iron status **(25)**. It has also been suggested in one of the study conducted in Nepalese children that anemic and iron deficient subjects have high risk of hypothyroidism as they are reported to have higher TSH than non-anemic subjects **(27)**. Similarly, a development of secondary and subclinical hyperthyroidism in a significant portion of patients with iron deficiency anemia has been reported in a clinical study conducted in adults with iron deficiency anemia **(28)**.

The present study is the first report to associate iron deficiency anemia with hypothyroidism in adolescent school going girls of local tribal community in Udaipur. The study do have limitation of small sample size, less number of parameters tested and the data of non school going girls of same age group. It is suggested that routine monitoring of thyroid function test and iron deficiency anemia in adolescent girls along with appropriate iron supplementations may reduce adverse pregnancy outcomes and mother mortality in their later life.

CONCLUSION

A considerable proportion of adolescent school going tribal girls had iron deficiency anemia. Nearly two-third girls were anaemic (Hb < 12 g/dl); anaemia was significantly more in girls belonging to bigger family size. All severely anemic girls were found to have thyroid dysfunction. Thus, there is a need for closely monitored implementation of intervention strategies and methodologies for tribal areas, as per the local socio-cultural context. An effort would be required to promote consumption of iron rich foods for long-term gains in iron status of the adolescent tribal girls. Various Interventions for anemic adolescent tribal girls may raise their iron stores and sustain their hemoglobin at normal levels. This will not only improve their physical and mental capacity, but also subsequently help in reducing the incidence of low birth weight of infants and maternal mortality rates. The results further indicated a need for longitudinal studies with larger sample size to be undertaken in different parts of the Southern Rajasthan to assess the magnitude of iron deficiency anemia and associated thyroid dysfunctions amongst school going adolescent girls of tribal community.

Umesh Pareek* Assistant professor, Biochemistry Department, Ananta institute of medical sciences and research centre, Rajsamand , Rajasthan, India *Correspondnig Author

ABSTRACT

Background: Vitamin D is a secosteroid hormone and well-known for its classical actions in the maintenance of calcium uptake and bone metabolism. Recently, numerous in vitro experiments demonstrated that 1,25-(OH)2D3, the active form of vitamin D, inhibited the growth and differentiation of human prostate cancer cells.
Aim: To estimate vitamin D level in prostate cancer patients along with increasing risk.
Material & Methods : 100 samples along with control were analysed by cobas e-411 for Vitamin D and PSA.
Results: we have found Higher risk of prostate cancer who having low vitamin D.
Conclusion: it's time to aware people for supplementation of Vitamin D, so we can prevent for the same.

KEYWORDS

Vitamin D, Prostate cancer, PSA, hypovitaminosis

INTRODUCTION:

Deficiency of vitamin D or hypovitaminosis D is widespread irrespective of age, gender, race and geography and has emerged as an important area of research Vitamin D deficiency is prevalent worldwide. This deficiency has many consequences which are still being explored, apart from the well-known skeletal complications. With the consequences of Vitamin D deficiency, namely, autoimmune diseases, cardiovascular diseases, cancer, and tuberculosis being explored. [1]. Vitamin D_3 deficiency continues to be an unrecognized epidemic in many populations around the world. Vitamin D is important for the absorption of calcium, and bone formation and maintenance [2] .The incidence of prostate cancer differs between countries due to coverage of prostate-specific antigen (PSA) screening [3]. patients with advanced-stage or metastatic cancer will ultimately progress to castration-resistant prostate cancer [4]. The mechanisms by which prostate cancer progresses to castration-resistant prostate cancer have been studied extensively [5]. Increasing evidence demonstrates that inflammation plays important roles in the pathogenesis of progression to castration-resistant prostate cancer [6]. A double-blinded clinical study found that vitamin D supplementation reduced prostate specific antigen (PSA) level and enhanced survival rate in patients with prostate cancer [7].

On the other hand, vitamin D receptor (VDR) polymorphisms were associated with the incidence of prostate cancer [7, 8]. Several epidemiological reports showed that men with vitamin D deficiency had a higher risk of prostate cancer compared to men with vitamin D sufficiency [9,10]. Nevertheless, the mechanisms through which vitamin D deficiency elevates the risk of prostate cancer remain unclear. The present study aimed to investigate whether there was an association among prostate cancer, vitamin D status in a hospital-based case-control study.

MATERIALS AND METHODS

A case control study done in Ananta institute of medical sciences and research centre, Rajsamand. During June 2016- November 2016. In the present study, total 50 newly diagnosed patients with prostate cancer were recruited as cases. Prostate cancer was confirmed by histopathology. 50 Controls were recruited from men undergoing physical examination. Vitamin D and PSA done by chemiluminescence immunoassay methodology. method on Cobas e-411 and chemistry (CRP) ,FBG, creatinine, uric acid, T.G., Total Cholesterol by Cobas Intigra 400^{+}. Serum samples of all cases and controls were collected at same season and stored at -20°C.

RESULTS

Biochemical characteristics were analyzed as shown in Table 1, no significant difference in Cr, UA, TG, TCH, fasting blood glucose was observed between cases and controls. As expected, serum T-PSA was significantly increased in patients with prostate cancer as compared with control subjects (Table 2).

Serum 25(OH)D concentration was analyzed in all subjects. As shown in Figure 1A, serum 25(OH)D in patients with prostate cancer was significantly lower than in controls.

Table 1

Parameters	Case(50)	Control (n=50)	P- value
FBG	70±1.2	69.12±.32	0.81 NS

PSA	3.70±2.36	15.12±1.25	<0.001*

*Significant change

DISCUSSION

The present study analyzed the association among prostate cancer, vitamin D status. Our results showed that serum 25-(OH) D was reduced in patients with prostate cancer. By contrast, serum CRP, a marker of systemic inflammation, was elevated in patients with prostate cancer. These results provide evidence for the first time that low vitamin D status is associated with inflammation in patients with prostate cancer.

Chronic inflammation promotes metastases and progression to castration-resistant prostate cancer [11, 12]. CRP could predict tumor aggressiveness and potential treatment efficacy in patients with prostate cancer [13]. According to an early report, CRP is an independent prognostic factor for overall survival of patients with castration-resistant prostate cancer treated with docetaxel [14]. A recent study showed that elevated CRP level was associated with poor prognosis in prostate cancer patients treated with radiotherapy [15]. Our results showed that serum 25-(OH)D level was lower in patients with severe prostate cancer than in patients with mild and moderate prostate cancer. By contrast, serum CRP was higher in patients with prostate . These results suggest that low vitamin D status is associated with inflammation and the progression of prostate cancer.

Increasing evidence indicates that vitamin D has an anti-inflammatory activity [16]. These results suggest that inflammation may be a key mediator for prostate cancer progression in patients with low vitamin D status.

The present study has several limitations. First, the present study did not observe whether vitamin D deficiency and inflammation promotes metastasis and progression of prostate cancer. Thus, additional study is required to investigate whether prostatic inflammation promotes prostate cancer in patients with low vitamin D status.

In summary, the present study investigated the association among prostate cancer, vitamin D status and inflammation. Our results showed that serum 25-(OH) D was decreased in patients with prostate cancer. By contrast, serum CRP was increased in patients with prostate cancer.

ABSTRACT

Mushrooms are known for good quality of protein; therefore *Pleurotus sajor-caju* was selected to study the essential amino acid content and the effect of supplementation of *Pleurotus sajor-caju* on growth of albino rats. Rats were randomly assigned on diet containing mushroom fruiting and mushroom mycelium for a period of 30 days. On every 10th day, animals were weighed and their diet intake, remnant food and protein intake were measured. The result showed phenylalanine, methionine, tryptophan, threonine, isoleucine, lysine and histidine values of mycelium found significantly more than fruiting. In animal experiment values showed significant difference in body weight between control and experimental groups. Study concluded that the feeding of mushroom fruiting and mushroom mycelium diets helped to gain weight of albino rats because of then excellent nutritional composition.

INTRODUCTION

There has always been lack of harmony between the rapidly growing world population and the adequate supply of protein rich foods in the human diet. The mushrooms, yeast and algae are frequently mentioned as an alternative source for food. Mushrooms have been valued throughout the world as both food and medicine for thousands of years (Lindequist *et al.,* 2005; Wright 2004; and Tribe *et al.,* 1973).

Mushrooms are considered as a good source of protein, vitamins and minerals (Jiskani, 2001). *P. ostreatus* and *Pleurotus sajor-caju* are contain protein (27.4% and 26.9% respectively), carbohydrate (40.75%) and low lipid (5.4 % and 6.2 %) on dry weight basis (Dhonda *et al.*, 1996; Rai *et al.* 1988). Chang and Miles (1989) have suggested that the protein in mushroom, in general, is about twice that in asparagus and cabbage, and 4 and 12 times those in oranges and apples, respectively.

All the essential amino acids required by an adult are present in mushroom (Bisaria *et al.*, 1987). Lintgel *et al.* (1994) reported the digestibility of mushroom protein to be as high as 72-83 per cent. Quality of mushroom protein is far superior to the vegetable proteins and it is as good as or just inferior to animal protein because of presence of essential amino acids (Crisan and Sands, 1978; Bano and Rajarathnam, 1982; Chang and Miles, 1989). Quality of protein is nutritionally more important than its quantity. Requirement of protein is infact the requirement of amino acids. Human body is incapable of producing essential amino acids. Mushrooms are well recognized for their protein quality. Keeping this in view fruiting and mycelium of oyster mushroom were analyzed for its essential amino acids content and the diet supplemented with *Pleurotus sajor-caju* was selected to feed albino rats to know the growth effect.

MATERIAL AND METHODS

The present study was conducted during 2006-2007 in the Department of Home Science, Sant Gadge Baba Amravati University, Amravati. Oyster mushroom spp. *Pleurotus sajor-caju* was selected because it is grown commercially in central India and cost of cultivation is low. Fruiting of oyster mushrooms was cultivated by polybag technique and mycelium was grown on agar-agar media. Fruiting and mycelium of oyster mushroom were harvested from bags and media, respectively. Both were dried at 32^{0}C temperature in the incubator. Fruiting and mycelium were ground to form fine powder. Powders were stored in airtight container. Fruiting and mycelium of oyster mushroom were subjected to analyzed essential amino acids by paper chromatography method (Thimmaiah, 1999). Oyster Mushroom diets were prepared out of fruiting and pure mycelium. Oyster mushroom diets (as shown in table 1) were fed to albino rats to study the effect on weight of albino rats.

About thirty male albino rats were obtained from Department of Biochemistry, Rastra Sant Tukdoji Maharaj Nagpur University, Nagpur. The weight of rats was between 50 to 60 grams and age was between 40 to 45 days. Rats were randomly divided to in five groups. Each group had 6 rats. Control diet was fed to first group of rats and rest four groups were kept on experimental diets. At the beginning of the experiment, all rats were fed with standard diet (Swaminathan, 1999) for one week. The observations about diet provided and left over were recorded. The duration of feeding experiment was 30 days, on every 10th day rats were weighed. Their diet intake, remnant food and protein intake were measured. The composition of control and experimental diets is given in table 1. Control diet does not contain mushroom fruiting or mycelium. Diet 1 and 2 comprise control diet and 1 and 2g oyster mushroom fruiting (OMF) respectively. Diet 3 and 4 contain control diet and 1and 2g oyster mushroom mycelium (OMM) respectively. Water was given in adlibitum.

Table 1: Composition of control and experimental diets

S. No.	Ingredients (g)	Control diet	Experimental diets			
			Diet 1 1g OMF	Diet 2 2g OMF	Diet 3 1g OMM	Diet 4 2g OMM
1	Wheat flour	20.00	19.00	18.00	19.00	18.00
2	Roasted bengalgram dhal	58.00	58.00	58.00	58.00	58.00
3	Groundnut flour	10.00	10.00	10.00	10.00	10.00
4	Skimmilk powder	04.00	04.00	04.00	04.00	04.00
5	Casein	04.00	04.00	04.00	04.00	04.00

RESULTS AND DISCUSSION

Oyster mushroom was analyzed to find out essential amino acids and estimated mean values are given in the table 2.

Table 2: Essential amino acids (% crude protein) in fruiting and mycelium of oyster mushroom

S. No.	Essential amino acids	Fruiting Mean ± SD	Mycelium Mean ± SD	't' value
1	Phenylalanine	4.00 ± 0.10	6.50 ± 0.10	10.00*
2	Valine	5.10 ± 0.10	4.30 ± 0.28	01.40
3	Methionine	2.20 ± 0.10	2.60 ± 0.37	02.00
4	Tryptophan	1.50 ± 0.10	2.10 ± 0.10	03.33*
5	Threonine	5.10 ± 0.10	7.50 ± 0.10	08.06*
6	Isoleucine	3.40 ± 0.10	4.20 ± 0.11	05.80*
7	Leucine	6.50 ± 0.10	5.20 ± 0.10	05.90*
8	Lysine	6.40 ± 0.10	7.00 ± 0.11	01.66
9	Histidine	2.10 ± 0.10	2.50 ± 0.01	00.86

* Significant at 0.05 level of probability

The fruiting and mycelium contained all essential amino acids but in varying amount. Fruiting contained 4.00 per cent and mycelium contained 6.50 per cent phenylalanine. It reveals that mycelium found to be better than fruiting in respect of phenylalanine which could be seen from the significant 't' value (10.00) at 5 per cent level of significance.

Valine present in fruiting and mycelium found to be 5.10 and 4.30 per cent, respectively. However, 't' value (1.40) reveals that there was no significant in the content of valine in fruiting and mycelium. Fruiting contained 2.20 per cent and mycelium 2.60 per cent methionine. This shows that both fruiting and mycelium were similar in methionine content, as could be seen from non significant difference between fruiting and mycelium at 5 per cent level of probability.

Fruiting and mycelium contained 1.50 per cent and 2.10 per cent tryptophan, respectively. Mycelium found to be better than fruiting in respect of tryptophan content as 't' value shows significant difference between fruiting and mycelium at 5 per cent level of significance.

Fruiting contained 5.10 per cent threonine and in mycelium it was found to be 7.50 per cent. It shows that mycelium found to be better source of threonine than fruiting as significant difference could be found between fruiting and mycelium at 5 per cent level of probability (t = 8.06).

Isoleucine present in fruiting was 3.40 and 4.20 per cent in mycelium. It indicates that the mycelium found to be better in isoleucine than fruiting, as 't' value (5.80) found to be significant at 5 per cent level of probability. Fruiting contained 6.50 per cent and mycelium contained 5.20 per cent leucine. Fruiting found to be better than mycelium in respect of leucine as significant difference could be noticed from the 't' value (5.90).

Fruiting contained 6.40 per cent lysine and mycelium contained 7 per cent lysine. Though mycelium showed high amount of lysine than fruiting but 't' value showed no significant difference between fruiting and mycelium and thus both are at par as far as lysine content is concerned.

Fruiting contained 2.10 per cent and mycelium contained 2.50 per cent histidine. Both fruiting and mycelium contained similar amount of histidine as no significant difference could be noticed (t = 0.86).

Animal experiment

The observed values of feeding experiment about total diet intake, total protein intake and the total gain in body weight on 10th, 20th and 30th day are given in tables 2, 3 and 4, respectively.

Table 2: Mean diet intake, protein intake, weight gain of albino rats on 10th day

S. No.	Diets	Protein g/100g diet	Actual diet intake (g) Mean ± SD	Actual protein intake (g)	Weight gain (g) Mean ± SD
1	Control	22.12	102.08 ± 2.91	22.67	22.50 ± 2.12
2	1g OMF	22.54	102.03 ± 1.67	22.99	22.58 ± 1.02
3	2g OMF	22.87	104.03 ± 2.95	23.79	27.24 ± 2.43
4	1g OMM	22.68	102.88 ± 2.50	23.33	24.50 ± 2.32
5	2g OMM	23.15	104.12 ± 4.02	24.10	29.18 ± 1.16

Data in table 2 indicates that the gain in body weight of rats kept on experimental diets was better than control diet. It was noted that the weight gain of rats fed on 2g OMF (27.24 ± 2.43) and 2g OMM (29.18 ± 1.16) was better than 1g OMF (22.58 ± 1.02) and 1g OMM (24.50 ± 2.32) diets. It was also observed that the gain in weight of rats fed on diet 1 and 2 comprise OMM was better than the diets 3 and 4 contains OMF. The results thus lead to the conclusion that higher the content of mushroom, better the weight gain. However, mushroom mycelium was found effective than the fruiting of oyster mushroom.

Table 3: Mean diet intake, protein intake, weight gain of albino rats 20th day

S. No.	Diets	Protein g/100g diet	Actual diet intake (g) Mean ± SD	Actual protein intake (g)	Weight gain (g) Mean ± SD
1	Control	22.21	110.12 ± 4.28	24.45	27.18 ± 3.51
2	1g OMF	22.54	112.02 ± 2.10	25.24	28.01 ± 2.51
3	2g OMF	22.87	118.16 ± 5.02	27.02	31.21 ± 1.15
4	1g OMM	22.68	112.78 ± 1.75	25.57	30.04 ± 1.52
5	2g OMM	23.15	115.21 ± 2.04	26.67	33.50 ± 2.64

Data in table 3 indicates that the highest weight gain of albino rat (33.50g) was observed in 2g OMM diet. Rats kept on control diet (27.18g) and 1g OMF diet (28.01g) showed low weight gain. The results showed that oyster mushroom mycelium was found better in increasing the body weight of albino rats and followed by OMF and OMM diets.

Table 4: Mean diet intake, protein intake, weight gain of albino rats on 30th day

S. No.	Diets	Protein g/100g diet	Actual diet intake (g) Mean ± SD	Actual protein intake (g)	Weight gain (g) Mean ± SD
1	Control	22.21	130.10 ± 2.32	28.89	29.01 ± 1.73
2	1g OMF	22.54	131.12 ± 3.98	29.55	28.50 ± 3.05
3	2g OMF	22.87	136.22 ± 3.23	31.15	33.48 ± 2.00
4	1g OMM	22.68	132.18 ± 2.05	29.97	31.50 ± 1.52
5	2g OMM	23.15	135.61 ± 4.01	31.39	36.11 ± 3.00

Perusal of data in table 4 reveal that the highest weight gain of albino rat (36.11g) was found in 2g OMM diet, relatively protein intake was 31.39g. One gram OMF supplemented rat group showed lower weight gain (28.50g) than control group (29.01g) but 2g OMF supplemented group showed better weight gain (33.48g) than 1g OMF fed group. The results thus lead to conclude that weight gain of rat fed on OMM diet was better than the OMF diet. As the amount of mushroom increases weight also increases. However, mushroom mycelium diet were found effective than the fruiting diet.

The data in respect of mean weight gain of albino rats on 10th day, 20th day and 30th day of control and experimental diets (1g and 2g OMF and OMM diets) have been presented in table 5 for comparison.

Table 5: Weight gain (g) of albino rats (control with 1g and 2g doses of fruiting and mycelium each)

S. No.	Days / Diets (n=6)	10th day	20th day	30th day	1st – 30th days
1	Control	22.50	27.18	29.01	78.69
2	1g OMF	22.58	28.01	28.50	79.09
3	2g OMF	27.24	31.21	33.48	91.93
4	1g OMM	24.50	30.04	31.50	86.04
5	2g OMM	29.18	33.50	36.11	98.79
	'F' Test	33.00*			

* Significant at 0.05 level of probability Two way ANOVA was applied for testing the significance of difference of means of control and experimental diets (1g and 2g OMF and OMM diets each) and data obtained have been presented in table 5.

Table 5 reveals that on 10th day the diet intake of albino rats were low, therefore, showed low weight gain. The plausible reason for low consumption of diet was albino rats were not accustomed to the diets. On 20th and 30th day, more weight gain was observed because of increased intake of diet and relative increase in protein intake. Overall weight gain pattern reflects that as diets comprising oyster mushroom increases body weight also increases. *In vivo* proteins are required for tissue development and oyster mushroom comprises good amount of protein. The 2g OMF and 2g OMM diets fed groups showed better weight as compared to 1g OMF and 1g OMM diets. Significant differences were found between weight gain of albino rats fed on different diets.

The quality of food protein depends upon its amino acid composition, especially that of essential amino acids. *In vivo* essential amino acids perform many functions but lysine, leucine, valine and histidine are especially required for growth and as such oyster mushroom comprise these four amino acids in good quantity as reported by Rai (1995).

Results show that the quality of protein depends on presence of all essential amino acids in food; as such oyster mushroom mycelium and fruiting contained all essential amino acids. The mean values of phenylalanine, tryptophan, threonine and isoleucine indicate that the content of these amino acid was definitely higher in mycelium than fruiting. Whereas, the fruiting of oyster mushroom definitely contained higher amount of leucine than the mycelium. The results of the animal experiment proved that the supplementation of oyster mushroom diets showed significant weight gain of albino rats. Thagumanaven and Maniekam (1980). Too observed weight gain in rats fed on *Pleurotus sajor-caju* due to its high digestibility. Similar result was also observed by Samajpati (1979).

CONCLUSION

Present investigation proved that the Oyster mushroom fruiting and mycelium contribute all essential amino acids. Phenylalanine, methionine, tryptophan, threonine, isoleucine, lysine and histidine values of mycelium found significantly more than fruiting. The supplementation of oyster mushroom helped to gain weight of albino rats because of its excellent nutritional composition.

Abstract **Original Research Article**

Background: Polycystic ovary syndrome (PCOS) is a complex endocrine disorder affecting 5–10 % of women of reproductive age. It generally manifests with oligo/anovulatory cycles, hirsutism and polycystic ovaries, together with a considerable prevalence of insulin resistance. ***Objectives:*** The objective of the study is to establish correlation among testosterone, insulin, FSH, LH and lipid profile among the women with polycystic ovary syndrome (PCOS), in order to evaluate their diagnostic and prognostic significance**.** ***Methodology:*** This study includes total 300 female participants of age Group between 18-40 year of age**.** They were divided in to two groups. Group 1(n=150) includes women having PCOD and Group 2(n=150) is control Group. Fasting Blood samples were obtained from all participants to measure Blood sugar, Lipid Profile insulin, HOMA-IR, Testosteron, FSH, LH and Prolactine**.** ***Result:*** The Mean level of S.Testosteron, S.FSH, S.LH, S.Prolactine and HOMA-IR Fasting Blood sugar, S.cholesterol, S, and Triglyceride S.Insulin is found to be Lower Control Group as compared to PCOD group and difference among them found to be statically significant. ***Conclusion:*** From our study I would like to conclude that a PCOS, as a syndrome, has got multiple components including reproductive, metabolic and hormonal, with long-term health concerns that cross the life span. Moreover, PCOS patients have a higher risk of metabolic and cardiovascular diseases and their related morbidity, if compared to the general population.

Key words: PCOD, Insulin, HOMA-IR, Testosteron, FSH, LH, Prolactine.

INTRODUCTION

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in women and major cause of anovulatory infertility. PCOS patients can present a wide range of signs and symptoms, which make difficult the precise grading of the condition. Diagnosis of PCOS is currently based on the criteria of the ESRHE/ASRM Rotterdam consensus meeting in 2003 [1], which broadened the previous NIH classification of 1990 [2]. It based on at least two of the following features: oligo-anovulation, hyperandrogenism and polycystic ovaries by ultrasound [1]. In 2006, the Androgen Excess Society (AES) set up a committee of experts to review all the data published on PCOS for the purpose of simplifying diagnosis [3]. The AES criteria require clinical and/or biochemical hyperandrogenism simultaneously with oligo/anovulation and ultrasonographic evidence of polycystic ovaries.

There is increasing evidence suggesting that PCOS affects the whole life of a woman, can begin in utero in genetically predisposed subjects, it manifests clinically at puberty, continues during the reproductive years. It can also expose patients to increased risk of cardiovascular disease, hypertension, diabetes and other metabolic complications, especially after menopause [4]. During the fertile period it may cause anovulatory infertility and could be associated with increased prevalence of gestational complications, such as miscarriage, gestational diabetes and preeclampsia [5]. Early diagnosis is therefore crucial by enabling close follow-up and in an attempt to reduce the risk of such complications.

Therefore, the present investigations will be carried out to assess testosterone, LH, FSH & insulin hormones level, HOMA-IR level. Subsequently regular assessing of sugar glucose, lipid profile and differential diagnosis of prolactin (PRL) in clinical biochemistry laboratory is important to monitor & study the effect of these parameters among normal and polycystic ovary Syndrome (PCOS) women & its adverse consequences.

MATERIAL & METHOD

This prospective study was conducted at Department of Biochemistry and Department of

Obstetrics & Gynaecology, Geetanjali Medical College & Hospital, Udaipur, Rajasthan, India from June 2012-Dec 2013. A total of 300 subjects of age group between 18-40 years belonging to both normal & polycystic ovary syndrome will be classified as:

Group-1:150 women with PCOD (Cases) of polycystic ovary disease will be taken.
Group-2:150 normal women will be taken as control for these parameters.

All PCOD women & controls were underwent a complete history and physical examination. Women with PCOD should be interviewed of their name, address, age, socio-economic status, and menstrual history, age of menarche, education level and family history of PCOD. All women were gone through gynaecological ultrasonography to determine their uterus and ovaried condition.

Inclusion Criteria

Women with PCOD are attending outdoor OPD of the hospital, first time diagnosed PCOD, Diagnosed polycystic ovarian syndrome, age ranging from 18-40 years.

Women with PCOD Willing to have physical examinations like Weight, Height, BMI, W/H ratio, Blood Pressure, Hirsutism, Acne, Dark patches, Virilization, Ultra sonography etc.

Polycystic ovary syndrome (PCOS) associated with Diabetes,obesity, Cardiovascular disorders. Irregular menstrual disorder and anovulation, Hirsutism & Acne symptoms.

Exclusion Criteria

Women with diagnosed adrenal hyperplasia, androgen secreting neoplasm, other pituitary (acromegaly) and adrenal disorders like Cushing syndrome, Virilizing adrenal or ovarian neoplasm**,** hyperprolactinemia and other infertility cause, Thyroid hormone related infertility, Women having history of smoking, taking alcohol or tobacco chewing**,** Any other type of gynaecologic complications except related with Polycystic ovary syndrome (PCOS) will be excluded from the study.

Fasting 10 ml venous blood samples were obtained from all participants and collected it in to fluoride and plain vaccutainer. An Uniq ID number was given to each sample to hidden the identity of participants. All samples were centrifugated at 3000 RPM for a period of 10 minutes to obtain a Plasma and serum.

Blood Glucose (FBS) measured by GOD POD method and lipid profile (S. Cholesterol, Triglyceride, HDL, VLDL, LDL) measured by enzymatic colorimetric method from all samples.

Fasting Insulin level estimation was done by enzyme linked immune assay (ELISA) method based electrochemilumnescence and HOMA-IR will be estimated by calculation (fasting sugar×fasting insulin/22.5).

Various Endocrinal Hormones like testosterone, LH, FSH, Insulin and Prolactine was measured by enzyme linked immune assay (ELISA) method based on electrochemilumnescence from all samples.

After assessing all the values, Mean, Standard deviation of all subjects & parameters were analysed. Statistical analysis was performed with SPSS software. Comparison between cases and with control is done by independent student's t test. By using't' values now P value is less than 0.05 (P value < 0.05), it is significant. Comparison of the categorical variables (among category comparison) was done by using Chi-Square test.

RESULTS & DISCUSSION

Infertility, hirsutism, and oligomenorrhea were more common among the subjects with PCOS, but there was a considerable spontaneous restitution of cyclic regularity with time. Women with PCOS were more often hysterectomized and entered menopause later compared with referents. The hormone data show a typical profile for PCOS. Compared with referents women with PCOS showed marked increase in prevalence of central obesity, higher basal serum insulin concentrations, and a higher prevalence of diabetes mellitus and hypertension [65].

Table-1: Age wise distribution of participants

Group	Number(n)	Mean Age(Yr)
Group 1(PCOD)	150	26.30 ± 5.0
Group 2(Control)	150	24.50 ± 4.13

Table-2: Location wise distribution of participants

Location	Group 1(PCOD)	Group 2(Control)
Rural	57(38%)	36(36%)
Urban	93(62%)	64(64%)

Graph-1: Showing Correlation of insulin & HOMA-IR between case and control group

- Comparison of the fasting basal sugar (FBS) between the two groups shows that FBS is higher (mean value = 106.7 ± 19.49) in Cases group than Controls (mean value = 96.1 ± 17.0 (Table 9).
- Comparison of the Triglyceride (TG) between two groups shows that TG is higher (mean value = 160.6 ± 36.98) than Controls (mean value = 154.6 ± 23.42). Comparison of Total Cholesterol (TC) between two groups shows that TC is higher (mean value = 189.1 ± 45.47) in Cases than Controls (Table 9).
- Comparison of the luteinizing hormone (LH) between two groups shows that LH is higher (mean value 147 ± 39) in Cases than Controls (mean value = 90.8 ± 43.6) (Table 10).
- Comparison of the follicular stimulating hormone (FSH) between two groups shows that FSH is higher (mean value 76.4 ± 45.6) in Cases than Controls (mean value = 22.2 ± 17.1) (Table 10).
- Testosterone is higher (mean value 13 ± 6.3) in Cases than Controls (mean value = 2.67 ± 1.4) (Table 10).
- Insulin hormone is higher (mean value 15.5 ± 6.2) in Cases than Controls (mean value = 7.4 ± 2.0) (Table 10).
- HOMA-IR is higher (mean value 75 ± 41.1) in Cases than Controls (mean value = 31.8 ± 10.6) (Table 10).

Although the exact cause of PCOS is unknown, it is understood to be a multifactorial condition with a genetic component. Approximately 20–40% of first-degree female relatives of women with PCOS go on to develop PCOS themselves, compared to estimated 4–6% prevalence in the general population [6]. Many women with PCOS have female relatives with PCOS, even if it was never diagnosed as with type 2 diabetes, it is likely that numerous genes each make a small contribution to the etiology of PCOS; and recent genome-wide association studies have identified candidate genes [7-9]. Any underlying genetic predisposition is likely complicated by epigenetic and environmental factors such as an unhealthy diet and lack of physical activity.

Clinically, PCOS may manifest as a mild menstrual disorder or a severe disturbance of reproductive and metabolic functions [10]. Most visible signs are caused by excessive production of insulin or androgens. Hirsutism (excess hair growth on the face and body) is present in ~ 70% of women with PCOS and is considered to be a good marker for hyperandrogenism but should be evaluated biochemically.

CONCLUSION

From our study I would like to conclude that a PCOS, as a syndrome, has got multiple components including reproductive, metabolic and hormonal, with long-term health concerns that cross the life span. Moreover, PCOS patients have a higher risk of metabolic and cardiovascular diseases and their related morbidity, if compared to the general population.

ABSTRACT

Background: Infectious diseases are a major cause of morbidity and mortality in children. One of the most cost-effective and easy methods for child survival is immunization. The objective of study was to assess the immunization coverage in the rural area of Dhule.
Methods: A community based cross-sectional study was conducted by using WHO 30x7 cluster sampling technique in Primary Health Centre, Kheda catchment villages among children aged 12-23 months on the day of survey. The total sample size was found out to be 210. Identification of clusters was done as per WHO manual on 30×7 cluster survey. Interviews were conducted as per a structured interview format in households with eligible children. Data feeding was done in MS Excel sheet.
Results: Full immunization coverage (FIC) was found out to be 58.6%. Drop-out rate was calculated to be 22.95%. The main reason for not completing the immunization was unaware to return for subsequent vaccine doses.
Conclusions: Coverage evaluation of vaccines was found out to be 58.6%. Drop-out rate is high.

Keywords: Immunization, Cluster sample, Coverage evaluation, Drop-outs

INTRODUCTION

Infectious diseases are a major cause of morbidity and mortality in children.[1] Globally, 3 million children die each year of vaccine preventable diseases. Most of these children reside in developing countries.[2] One of the most cost-effective and easy methods for child survival is immunization.[3] Though all efforts are put in, by the governmental and non-governmental agencies, there are pockets of low coverage areas.[1]

Based on DLHS-4 study conducted by the Government of India and published in 2012-13, in rural area of Maharashtra, the percentage of children aged 12-23 months who were fully immunized was 67%.[4] Further, partially immunized and unimmunized children are more susceptible to childhood infectious diseases.[5]

The present study was planned to evaluate the coverage of vaccines using WHO 30×7 cluster sampling technique in the catchment villages of primary health center, Kheda in district Dhule, Maharashtra. The objective of the study was to assess the immunization coverage in the rural area of Dhule.

METHODS

The Catchment villages of primary health centre, Kheda, Dhule, Maharashtra were the survey setting while, coverage evaluation by WHO 30x7 cluster survey was the survey design for the study.

The standard WHO 30x7 cluster survey method was used to evaluate the immunization coverage.[6] This is a cluster sampling technique. Cluster sampling requires that samples be taken from only a sample of the subgroups. The 30×7 cluster sampling is often referred to as "two-stage sampling". The first stage of the sampling is probability proportionate to size (PPS) and the second stage is random. Children aged 12–23 months on the day of survey were the target age group. Since this survey was conducted to represent the most recent performance of the immunization system, the youngest possible children were chosen. Children aged 12–23 months are usually the most commonly chosen target population. The determination of sample size was done as per the WHO "Immunization coverage cluster survey".[6] For sample size determinations to estimate the coverage, the following were determined, estimated or assumed beforehand:

- Anticipated level of immunization coverage
- Desired precision of the estimate
- The level of statistical confidence of the estimate (confidence level)
- Magnitude of differences of coverage among and within the clusters (design effect)

The total sample size was estimated (the total number of children to be surveyed) using the equation below.

$$n_{min} = DE \times \frac{z^2 1-\alpha/2 \times p \times (1-p)}{d^2}$$

The minimum total sample worked out to 192. Since we were going to use 30 clusters, the sample size per cluster worked out to 192 ÷ 30 = 6.2. Rounded off, number of children to be surveyed in each of the 30 clusters was 7. Thus 210 children was the total sample size for 30 cluster survey. The study was conducted from 2nd November 2015 to 14th November 2015.

A cluster is a collection of households with identifiable geographical boundaries. The clusters used for this immunization coverage assessment were villages under PHC Nakane. Based on the projected 2016 village wise population, cumulative populations, sampling interval and selection of random number, all the 30 clusters were identified. The details of cluster selection were done as per WHO 30X7 cluster survey.[6] Survey tools and data entry tools were developed. Inputs and comments were taken. Pre-testing of the survey tools was done on the day of the field coordinators' orientation, before the field survey. Pre-tested in the field was done by same field coordinators who conducted the field activities of the survey under supervision. No major concerns came up regarding the survey tools during the pre-testing.

MS Excel based data management tools were developed. The pre-testing was done by entering data collected during pre-testing of survey tools.

The field implementation for the survey was conducted as per a detailed plan devised beforehand. Establishing of households of the selected clusters was not going to be possible. Therefore the core team decided that in every cluster, the geographical center of the cluster would be visited. From there, the investigators (FCs and Supervisor) would move in a randomly chosen direction. The first house would be the house corresponding to a random number chosen beforehand. Both, the direction in which the investigator would move and the random number for choosing the first house, were generated using the computer for each cluster.

After visiting the first household the second household to be visited was the one that was nearest to the first. The nearest household is defined as the household reachable in the shortest time on foot from the household just visited. The nearest household need not be in direct line of vision or on the same side of the street or road. If there are two or more households equally near to the one just visited, select the one on the immediate right as one stands in the doorway of the house looking out. Interviews were conducted as per a structured interview format in households with eligible children. Each investigator was directly supervised by a supervisor during each interview. The child was considered as fully immunized if he/she has received a dose of BCG, 3 doses of DPT and OPV and a dose of Measles vaccine. The child was considered as unimmunized if he/she did not receive any of these vaccines and partially immunized if some vaccine doses were given.

Data entry was done internally. A strict 3-stage quality check mechanism instituted –

- Every format submitted by FCs was scrutinized by survey focal point; most errors and omissions could be corrected at submission point.
- In-built checks and balances were introduced in the data entry tool at the time of development.
- 10% random check of entered data against actual forms.

RESULTS

Table 1 indicates the distribution of 30 clusters among all the 12 villages under PHC, Kheda catchment areas. The sampling interval was calculated out to be 1282 and random number was 1117. The total population covered by the PHC was 38465. Bigger villages namely; Morane, Chaugao and Kheda had 4 or more clusters.

Out of the 210 children, 51% were male, 43.8% were the 1st child, 73.3% had institutional delivery, only 42% had their immunization cards available and parents were mostly literate. Further, 77% resided in a joint family (Table 2).

The percentage of children who were fully immunized, partially immunized and unimmunized was found out to be 58.6%, 37.1% and 4.3% respectively. The coverage evaluation among various variables is also given in the Table 3.

The Table 4 shows distribution of availability and non-availability of immunization cards based on the sex of the child. Out of the 88 children having cards available, 53.4% were male.

Out of the 113 children not having cards available, 48.7% were male. 9 children had no card as they were unimmunized .

BCG coverage was 93.3%. Measles coverage was 71.9%. Drop-out rate (BCG to Measles) was 22.95% (Table 5).

Unaware of need for returning for subsequent doses was the reason among 60.3% of children who were partially immunized (Table 6).

DISCUSSION

The WHO 30×7 cluster sampling technique for evaluating vaccine coverage among children has been found to be very useful, convenient and operationally feasible by the investigators and public health administrators in developing countries. This technique allows a small number of the target population to be sampled while providing statistically valid data that can be extrapolated to the whole population.

In the current community based survey in the rural area of Dhule, Maharashtra, the percentage of children who were fully immunized, partially immunized and unimmunized was found out to be 58.6%, 37.1% and 4.3% respectively.

The District Level Health Survey-4 (DLHS-4) study conducted by the Government of India and published in 2012-13 showed that in rural area of Maharashtra the percentage of children who were fully immunized, partially immunized and unimmunized was found out to be 66.7%, 31.5% and 1.8% respectively [4]. Our findings are lower than the state average for fully immunized, partially immunized and unimmunized children. Our findings also revealed that the percentage of children belonging to ST (schedule tribe) who were fully immunized, partially immunized and unimmunized was 22.7%, 65.2% and 12.1% respectively which is strikingly much lower than the other population. Additionally, Dhule has a larger proportion of ST population. We would like to suggest it to be one of the possible explanations of lower coverage of vaccines in our study than the state average.

To the best of our knowledge and extensive review of literature we did not find any study on coverage evaluation of vaccines in Dhule, Maharashtra. So we were not able to compare our findings with other studies of the region. However, a similar study conducted by Jatti et al in Miraj, Maharashtra revealed that 60.5% children were fully immunized.[2] Negligence of parents towards immunization was the main reason for incomplete immunization in their study. Our findings show that unaware for the need of returning for subsequent doses was the main reason for not completing immunization in 60% of children.

A study conducted by Gupta et al in rural area of Pune, Maharashtra revealed that the fully immunized children were 83.6%.[1] While, Malkar et al in a study in rural area of Beed, Maharashtra concluded that 78.5% children were fully immunized.[7] Goyal et al in a study in rural area of Haryana showed the fully immunized and partially immunized percentage to be 73.15% and 23.85% respectively.[3] However, Pandey et al in their study found that fully immunized and partially immunized to be 76.19% and 22.86% respectively.[5]

BCG coverage in our study was found out to be 93.3%. Similar findings are reported by DLHS-4 study for Dhule and Maharashtra as well.[4] Jatti et al and Pandey et al in their studies also reported the BCG coverage to be around 93%.[2] BCG to Measles drop-out rate was calculated to be 22.95%. Similar higher rate of drop-out was reported by Jatti et al.[2]

Higher drop –out rate indicates the failure of the parents to bring their children for subsequent vaccine doses. Our study highlights that the parents/mother were unaware to return for subsequent vaccine doses as the main reason for not completing the immunization was. It emphasizes the importance of health workers providing vaccination

services to inform and reinforce the mother/parents to return for subsequent vaccine doses.

Our study also shows an association between sex of child, birth order, place of delivery, availability of vaccine card, social category of child, educational status of mother and immunization status of child. Higher rate of FIC (full immunization coverage) was found in male child, 1st birth order child, child born in an institution, mother having vaccine card, social category except SC and ST and literate mother.

CONCLUSION

Coverage evaluation of vaccines was found out to be 58.6%. Drop-out rate is high. Unaware to return for subsequent doses of vaccines was the main reason for high drop-out. Schedule tribe seems to be socially excluded among all the social categories as far as immunization coverage is concerned. Further, male child, 1st birth order, child born in an institution, mother having vaccine card and literate mother improved immunization coverage. Though, it requires further testing.

ABSTRACT

Background: Travelers play a significant role in the spread of infectious diseases across international borders, through their travel patterns and behaviors. Travel may be the only risk factor for infectious diseases that are well controlled in the travelers' country of residence, particularly vaccine-preventable diseases. **Objectives:** The aim of this study is to assess the knowledge and practice of travel vaccination and malaria prophylaxis among resident doctors of BJ Medical College and Civil Hospital, Ahmedabad. **Materials and Methods:** This was a cross-sectional study conducted at Civil Hospital and BJ Medical College, Ahmedabad. The study was conducted from July 2017 to October 2017. A pilot study was conducted among 20 resident doctors, and the prevalence of knowledge of travel vaccination was found to be 65%. Using the formula $4pq/L^2$, data were collected from 100 resident doctors. Data were collected using a semi-structured questionnaire, and data analysis was performed using Microsoft Excel 2013 and EpiInfo 7. For statistical analysis, Chi-square test was applied. Ethical consent was taken from all respondents. **Results:** 86% of the resident doctors were having knowledge about travel vaccination, and 79% were knowing about the requirement of malaria prophylaxis given to travelers. The travel vaccine knowledge was 100% among the persons above 30 years of age, and it was 86% in the younger age group (20–25 years). Country-wise knowledge about travel vaccination was more for developing countries than developed countries. Only 8.3% gave the history of taking immunization for international travel. Reasons for not taking immunization were not required for country of travel followed by non-awareness. **Conclusion:** The knowledge of travel vaccine and malaria prophylaxis was more among the 30+ age group followed by 20–25 age groups, and the knowledge of both was more among males. The practice of travel vaccination was found to be poor.

KEY WORDS: Travel Vaccination; Malaria Prophylaxis; Resident Doctors

INTRODUCTION

Travelers often play an important role in the spread of infectious diseases across borders, through their travel plans, behaviors, and patterns. Traveling might be the only risk factor for the transmission of infectious diseases that are well controlled in a certain country, especially vaccine-preventable diseases. The role of vaccination among travelers is a significant component for the prevention of travel associated infectious diseases.[1,2]

Health risks associated with travel need to be balanced against the positive opportunities offered by inter-regional and cross-border travel.[3] The main goal of travel health and associated fields is to protect travelers from disease, accidents, and death. International travel has seen a dramatic rise during

recent times, and there has been an increase in diseases and associated public health problems. Each year, around 80 million travelers from developed countries visit developing countries where the epidemiological and sanitary conditions are different from their country of residence.[4] Thus, travelers increase the risk of exposure to travel associated health problems which include infectious diseases that may be imported back to their home country.[5]

Immunizations taken before traveling contribute to the risk reduction of specific diseases for the traveler as well as the reduction in risk of international spread of diseases. Agent, host, and environmental factors determine the risk of acquiring a disease when traveling. Most significant factors are the place that has to be visited, travel duration, and reason for travel. Among host factors, the traveler's health and his/her behavior overseas have to be considered. As a result, an agent–host–environment-based assessment of the travel plan should be done when considering which immunizations are to be taken by the traveler.[6]

India has become a popular destination for tourists in South Asia. Recent economic opportunities have resulted in a remarkable increase of business-related travel. People traveling to India can be broadly divided into the business traveler, the young economical backpacker, the medical volunteer, the holiday tourist, and the immigrant or non-resident Indian visiting family and friends. Medical graduates in India are showing interest in international travel to different countries for higher specialist courses, career growth, and better opportunities. People traveling to India are at an intermediate risk for malaria, and recent reports in the rise of chloroquine-resistant *Plasmodium falciparum* malaria in various parts of India are causing a rise in concern. Furthermore, different international travel advisory bodies vary on their opinion for malaria prophylactic regimens to be followed when traveling to India.[7-9]

Improvement in the knowledge and health education of disease transmission among travelers, following recommendations on sanitation, food, and water hygiene, avoiding arthropod bites with physical barrier methods and insect repellents, chemical prophylaxis against malaria, and taking required vaccinations are all known to reduce the risk of travel-associated diseases.[10] Since a considerable amount of travelers are at risk for having a travel-related illness or injury during their outings, there is a need for travelers to seek suitable pre-travel health education and immunizations to reduce the risk of any ailment while away from their country of residence.[11]

Objectives

The objective of this study is to assess the knowledge and practice of travel vaccination and malaria prophylaxis among resident doctors of BJ Medical College and Civil Hospital, Ahmedabad.

MATERIALS AND METHODS

A cross-sectional study was conducted at BJ Medical College and Civil Hospital, Ahmedabad. The study was conducted from July 2017 to October 2017.

A pilot study was conducted among 20 resident doctors, and the prevalence of knowledge of travel vaccination was found to be 65%. Using the formula $4pq/L^2$, data were collected from 100 resident doctors of Civil Hospital and BJ Medical College, Ahmedabad.

Data were collected using a semi-structured questionnaire, and data analysis was performed with Microsoft Excel 2013 and Epi Info 7. For statistical analysis, Chi-square test was applied. Ethical consent was taken from all respondents.

RESULTS

Figure 1 shows that 86% of the respondents had knowledge about travel vaccination while 79% of the respondents had knowledge about malaria prophylaxis.

As per the practice of travel vaccination, of the 24% who traveled, only 2 (8.3%) gave the history of taking immunization. Reasons for not taking immunization were not required for country of travel followed by non-awareness.

Table 1 shows that knowledge about travel vaccination was more in the 30+ age group (100.0%) followed by

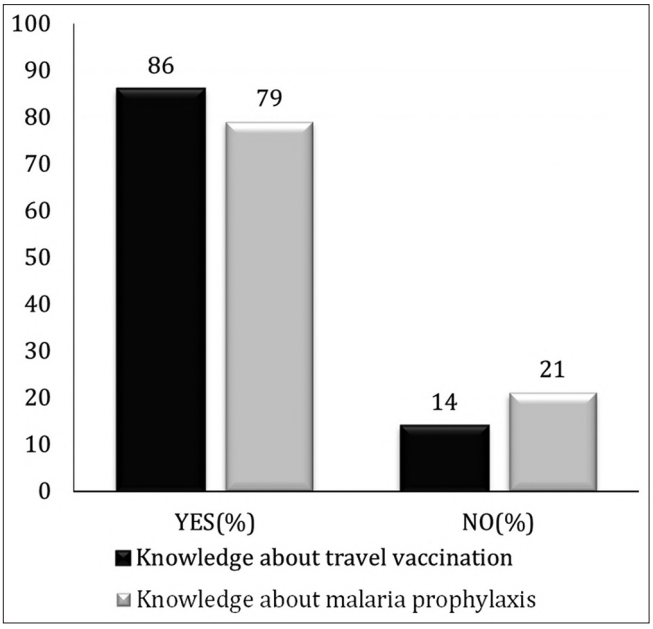

Figure 1: Overall knowledge about travel vaccination and malaria prophylaxis

Table 1: Relation of knowledge about travel vaccination with sociodemographic variables

Parameters	Respondents			
	Total	Having knowledge *n* (%)	Not having knowledge *n* (%)	*P* value
Age Group				
20–25	51	44 (86.3)	7 (13.7)	*P*=0.76
26–30	41	34 (82.9)	7 (17.1)	
30+	8	8 (100.0)	0 (0)	
Sex

Female	49	40 (81.6)	9 (18.4)	
Marital status				
Unmarried	72	61 (84.7)	11 (15.3)	*P*=0.79
Married	28	25 (89.3)	3 (10.7)	
Qualification				
1st-year resident	49	42 (85.7)	7 (14.3)	*P*=0.99
2nd-year resident	25	21 (84.0)	4 (16.0)	
3rd-year resident	26	23 (88.5)	3 (11.5)	

Table 2: Relation of knowledge about malaria prophylaxis with sociodemographic variables

Parameters	Respondents			
	Total	Having knowledge *n* (%)	Not having knowledge *n* (%)	*P* value
Age group				
20–25	51	44 (86.3)	7 (13.7)	*P*=0.18
26–30	41	28 (68.3)	13 (31.7)	
30+	8	7 (87.5)	1 (12.5)	
Sex				
Male	51	43 (84.3)	8 (15.7)	*P*=0.18
Female	49	36 (73.5)	13 (26.5)	
Marital status				
Unmarried	72	57 (79.2)	15 (20.8)	*P*=0.95
Married	28	22 (78.6)	6 (21.4)	
Qualification				
1st-year resident	49	40 (81.6)	9 (18.4)	*P*=0.47
2nd-year resident	25	17 (68.0)	8 (32.0)	
3rd-year resident	26	22 (84.6)	4 (15.4)	

the 20–25 years age group (86.3%) while those in the 26–30 years age group (82.9%) had the least knowledge. Knowledge was more in males (90.2%) compared to females (81.6%). Married respondents showed more knowledge (89.3%) compared to single respondents (84.7%). Knowledge about travel vaccination was highest among 3rd-year resident doctors (88.5%), followed by 1st-year residents (85.7%) and then 2nd-year Residents (84.0%).

Table 3: Country-wise knowledge about travel vaccination was more for developing countries than developed countries

Region	Percentage
USA	6
Europe	5
Australia	16
Africa	49
Southeast Asia	18
Arabian countries	13

However, no statistical significance was found between the sociodemographic variables with knowledge about travel vaccination ($P > 0.05$).

Table 2 shows that knowledge about malaria prophylaxis was more in the 30+ age group (87.5%) followed by the 20–25 years age group (86.3%) while those in the 26–30 years age group (68.3%) had the least knowledge. Knowledge was more in males (84.3%) compared to females (73.5%). Single respondents showed more knowledge (79.2%) compared to married respondents (78.6%). Knowledge about travel vaccination was highest among 3rd-year resident doctors (84.6%), followed by 1st-year residents (81.6%) and then 2nd-year residents (68.0%). However, no statistical significance was found between the sociodemographic variables with knowledge about malaria prophylaxis ($P > 0.05$).

Table 3 shows that country-wise knowledge about travel vaccination was more for developing countries compared to developed countries with that for Africa being the highest (49%) and that of Europe being the least (5%).

Figure 2 shows that 71% of the respondents were aware about the malaria chemoprophylaxis drug regimen compared to 29% which were unaware.

DISCUSSION

In our study, 86% of the respondents had knowledge about travel vaccination while 79% of the respondents had knowledge about malaria prophylaxis. In a similar study conducted in Nigeria, the knowledge about travel vaccination was found to be 96.3%.[1]

Most respondents were between 20 and 25 years of age, while in other similar studies conducted in Nigeria, Qatar, and America, majority of the respondents were of a higher age.[1,5,12] This study has an almost equal proportion of male and female respondents which is similar to an American study.[12] On the other hand, the number of male respondents were predominant in studies conducted in Nigeria and Australia, while the number of females were more in a Qatar

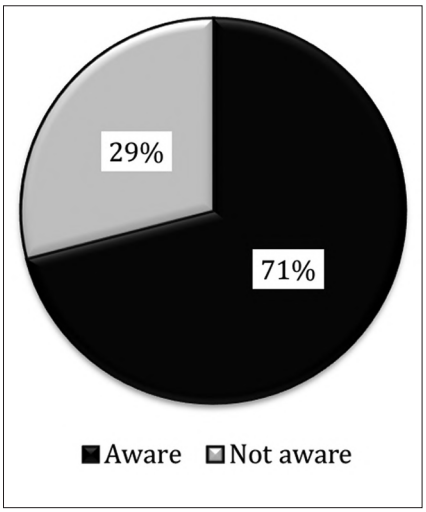

Figure 2: Awareness about malaria chemoprophylaxis drug regimen

study.[1,5,13] Most of the respondents were single which was contrary to a study conducted in Nigeria where most of the respondents were married.[1]

The practice of travel vaccination in this study was found to be very low which was similar to the findings of an Australian and Bangkok study but different from Greek and Nigerian studies where the practice of travel vaccination was found to be high.[1,2,13,14] Reasons of low practice in this study were not required for country of vaccination followed by non-awareness, while in other studies, the reasons were paucity of information on travel vaccination, distressing protocols and requirement for the vaccination, cost of vaccination as well as poor monitoring system for ensuring travel vaccination at the entry and exit points of the countries, unaware of being at risk, low knowledge of vaccination being important for traveling, cost of the vaccination, and side effects.[1,10,14]

The knowledge about travel vaccination and malaria prophylaxis was found to be good in this study which was similar to the results of other studies.[1,5,10,12-15]

Strength

The relation of sociodemographic variables with knowledge about travel vaccination and malaria prophylaxis is compared which has not been done in similar studies.

Limitation

The relation between knowledge about travel vaccination and malaria prophylaxis with sociodemographic variables was found to be insignificant, so the study should be carried out by taking a larger sample.

Recommendations

Doctors need to be updated on the latest norms of travel vaccination and malaria prophylaxis with special emphasis to be given on the importance of the practice of vaccination during international travel. This may be added to the academic curriculum because many doctors are interested in international career prospects.

CONCLUSION

It seems that the knowledge of travel vaccine and malaria prophylaxis was more among the 30+ age group followed by 20–25 age groups, and the knowledge of both was more among males. The married doctors showed more knowledge about travel vaccines, but the knowledge of malaria prophylaxis was more among single doctors. 3rd-year residents had more knowledge about both. The above groups may be more aware as they may be contemplating foreign travel in the near future. The practice of travel vaccination was found to be poor. Overall knowledge of travel vaccination and malaria prophylaxis was good.

An Epidemiological Study to Assess Prevalence and Risk factors Associated with Diabetes Among Adolescents in Urban Areas of Udaipur

Mitin Parmar[1], Gourav Kumar Goyal[2], Kalika Gupta[3], Milan Chaudhary[4]

[1]Associate Professor, [3]Assistant Professor, [4]Senior resident, Department of Community Medicine, [2]Assistant Professor, Department of Paediatrics, Ananta Institute of Medical Sciences and Research Centre, Rajsamand, Rajasthan

Correspondence : Dr. Kalika Gupa, Email : kalikagupta007@gmail.com

Abstract:

Introduction: Adolescents constitute 20% of world's total population. Adolescents have become quite vulnerable to various non-communicable diseases (NCDs) like hypertension and diabetes mellitus, especially due to the tremendous changes in their lifestyle over the last few decades. The age of onset of Type 2 diabetes in India has been shifting towards ever younger people. Among Indians in their late teens [15-19 years], Type 2 diabetes already manifests itself more often than Type 1 diabetes does. **Objective:** To study prevalence and risk factors for Type 2 diabetes and pre diabetes among male and female adolescents in Udaipur city. **Method:** It was a Community based cross sectional study conducted in three urban areas of Udaipur for 6 months. A total of 1005 adolescents were included in the study. A pretested and predesigned questionnaire was used. **Results**: Prevalence of diabetes was 2.9% in males and 4.4% in females adolescents. Prevalence of smoking, alcoholism, non-vegetarian diet and hypertension was higher among males. **Conclusion:** Diabetes type 2 is a growing problem among adolescents. We need active involvement of health care workers for educating adolescents about risk factors for diabetes.

Key words: Adolescents, Diabetes, Pre-Diabetes.

Introduction:

According to the WHO, adolescence is defined as the period between 10 to 19 years, the second decade of life. This is a period of rapid growth and development for adolescents' bodies, minds and social relationships.[1] Adolescence is a process whereby an individual makes the gradual transition from childhood to adulthood and is a critical period of development, second only to the early childhood years. Adolescents constitute 20% of world's total population.[2]

According to 2011 Census of India, there are 253.2 million adolescents constituting 20.9% of the total population.[3] This number is ever increasing making it the largest generation to undergo transition from children to adults in the near future, in turn making India the youngest country of the world.

Adolescents have become quite vulnerable to various non-communicable diseases (NCDs) like hypertension and diabetes mellitus, especially due to the tremendous changes in their lifestyle over the last few decades. Over half of NCD related deaths are associated with behaviours that begin or are reinforced during adolescence, including tobacco and alcohol use, poor eating habits, and lack of exercise, compounded by the presence of obesity.[4]

Quick Response Code	Access this article online	How to cite this article :
	Website : www.healthlinejournal.org	Parmar M, Goyal G K, Gupta K, Chaudhary M. An Epidemiological Study to Assess Prevalence and Risk factors Associated with Diabetes Among Adolescents in Urban Areas of Udaipur. Healthline. 2021; 12 (1):22-28
	DOI : 10.51957/Healthline_170_2020	

Diabetes Mellitus (DM) is a chronic disorder characterized by raised blood sugar levels that occur when the pancreas does not produce enough insulin or when the body cannot effectively use the insulin it produces.[5] The International Diabetes Federation has estimated that about 382 million people all over the world suffer from diabetes. If these trends continue, by 2035, about 592 million people, or every tenth person, will have diabetes.[6] In India, the overall diabetes prevalence is 8%. Prevalence is only 0.7% for non-obese, physically active, rural Indians. It reaches 11% for obese, sedentary, urban Indians.[7] There are about 1 million juvenile diabetics in India, and every year 12000 diabetic children [2-14 years] die of the disease.[8]

Global and national estimates for the prevalence of diabetes in the adolescent age group are unavailable till date. In the United States, May et al found out that the combined prevalence of prediabetes & diabetes in American adolescents was 23% in 2007-2008.[9] The largest study in India was conducted by Singh et al among 10,843 adolescents in Chandigarh during the year 2007, and they detected a prevalence of diabetes of 4.2%.[10]

Although Type 1 diabetes is the most common form in children, Type 2 diabetes poses a major health problem globally, especially in the developing world. The age of onset of Type 2 diabetes in India has been shifting towards ever younger people. Among Indians in their late teens [15-19 years], Type 2 diabetes already manifests itself more often than Type 1 diabetes does.[11] Type 2 diabetes in children and adolescents is probably under-diagnosed because it can exist without symptoms. The clinical manifestations of T2DM are preceded by an asymptomatic prodromal period called 'prediabetes'.

Against the above background, the present study was carried out with the objective to study the prevalence of diabetes and associated risk factors among individuals in the age group 10-19 years in urban areas of Udaipur, Rajasthan.

Method:

Study Design : Community based cross sectional study.

Study Area : The study was conducted in three urban areas of Udaipur – Bhuwana [population 17660], Fatehpura [2 lakhs population] and Siphon [10000 population]. The three areas were selected as they are catered by the Department of Community Medicine of the medical college.

Study Period : Study was conducted for a period of 6 months from July 2019 to December 2019.

Study Subjects : Males and females of 10-19 years residing in these areas

Sample Size : At 95% confidence level and taking the prevalence of diabetes and prediabetes to be 9.5% with a relative error of 20%, the sample size came out to be 934 using the formula

$\mathbf{n = Z_\alpha^2\, p\, q\, /\, L^2}$,

Where n = sample size

Zα = 1.96 value of the standard normal variate corresponding to level of significance alpha 5 %

p = prevalence of diabetes[12], 9.5%

q = 100 – p, 90.5%

L = precision, 20%

Accounting for a non-response rate of 20%, a total of 1027 subjects were to be included. Out of these, 22 did not give consent to be part of the study, hence 1005 adolescents were included in the study. By simple random sampling, subjects were selected from the three areas. Proportionate probability sampling was followed.

Inclusion Criteria :

1. All males and females of 10-19 years after getting consent from them and informed written consent from their parents if they are <18 years, or after getting consent from them if they are 18 years or older.
2. The person should be a resident of the area mentioned above for a minimum of 6 months.

Study Instruments : A predesigned, pretested, semi-structured questionnaire containing items on (a) identification data i.e. age, gender, religion, educational status, area of residence, socioeconomic status of the person, (b) risk factor for diabetes i.e. obesity, sedentary lifestyle, smoking, alcohol, family history, dietary habits, history of consanguinity, etc. The questionnaire was pilot tested among 20 adolescents in the village of Delwara in June 2019, and questions were later modified to ensure that the subjects would have no difficulty in understanding and answering them. Glucometer, digital sphygmomanometer, measuring tape and weighing scale were used in the study. Following criteria were used.

Hypertension: The hypertension status of the study participants was assessed by using standard criteria formulated by the American Health Association (AHA) -2017.[13]

Diabetes criteria: Blood sugar determination (fasting) was done by glucometer by glucose oxidase

Table 1: Socio-demographic profile of study subjects

Characteristics	Total [n=1005]	
	Males [n=527] n (%)	Females [n=478] n (%)
Age (years)		
10-14	271 (51.4)	236 (49.4)

Sikh	17 (3.2)	10 (2.1)
Christian	5 (1)	8 (1.7)
Education		
Illiterate	0	0
Primary/ Just literate	27 (5.1)	43 (8.9)
Middle School	198 (37.6)	182 (38.2)
High School	227 (43.1)	219 (45.8)
Intermediate/Diploma	75 (14.2)	34 (7.1)
Occupation		
Student	403 (76.5)	353 (73.9)
School dropout	22 (4.2)	80 (16.7)
Unskilled worker*	78 (14.8)	27 (5.7)
Semi-skilled worker**	24 (4.6)	18 (3.8)
Marital Status		
Married	12 (2.3)	56 (11.7)
Unmarried	515 (97.7)	422 (88.3)

*Unskilled worker: Person who are doing work which requires neither education nor specialized training.

**Semi-skilled worker: person who are doing work which requires some training to know their routine jobs efficiently.

method as per WHO and were interpreted. In the case of fasting plasma glucose (FPG) > 126mg /dl, a second determination was performed.[14]

Obesity criteria: Body mass index of the person was calculated using height and weight by applying the formula weight (in kgs) divided by square of height (in m^2).The cutoff criteria are based on the WHO BMI-for-age growth charts. Adolescents with BMI values at or above the 95th percentile of the sex-specific BMI growth charts are classified as obese.[15]

Ethical clearance and analysis: Institutional ethical clearance was taken. [No. AIMS/IEC/2019/022]. Statistical analysis was done using SPSS version 21.0.

Results:

Table 1 shows Majority of the subjects, 403 (76.5%) males and 353 (73.9%) females, were students. It was found that 22 (4.2%) males and 80 (16.7%) females were school dropouts and not doing anything. Out of 527 males, 24 (4.55%) and 78 (14.8%) were semi-skilled and unskilled workers respectively. It was also observed that, 12 (2.3%) males and 56 (11.7%) females were married, thereby highlighting the high prevalence of teenage marriage among adolescent girls. [Table 1]

Table 2 highlights that the prevalence of diabetes was 2.9% in males and 4.4% in females but the difference was not statistically significant (χ^2=3.66, p value 0.16)

Table 3 shows prevalence of smoking, alcoholism, non-vegetarian diet and hypertension was higher among males as compared to females. However, the difference was significant only for smoking (χ2=13.93, p value<0.001), alcoholism (χ2=36.76, p value<0.001) and non-vegetarian diet (χ2=4.51, p value 0.03).

Table 2 : Prevalence of diabetes among the study subjects

Table 4 highlights that subjects of 15-19 years age group experienced 2.03 times greater risk of getting diabetes as compared to subjects in the age group of 10-14 years (p value 0.02). Subjects who were obese experienced 1.86 times greater risk in comparison to those who were not obese (p value 0.05). Subjects with a positive family history of diabetes experienced 2.16 times greater risk of getting diabetes (p value 0.01). Subjects who led a sedentary lifestyle experienced 1.90 times greater risk of getting diabetes as compared to those engaged in moderate activity (p value 0.05). Subjects who were hypertensive experienced 1.79 times greater risk as compared to those who were not hypertensive (0.05).

Discussion:

The prevalence of diabetes in the present study was observed to be 3.6% among study subjects (2.9% in males and 4.4% in females) while the prevalence of prediabetes was observed to be 6.1% among the study subjects (5.1% in males and 7.1%

in females). Hence, the combined prevalence of diabetes and prediabetes among the study subjects was observed to be 9.7%. This was observed to be higher than that in the previous studies conducted by Ramachandran et al[16] among adolescents [12-19 years] in Chennai in 2007 (combined prediabetes and diabetes prevalence of 5.8%), by Singh et al[10] among 10,843 schoolgoing adolescents in Chandigarh in 2007 (4.2% prevalence of diabetes and 1.6% prevalence of prediabetes), by Balagopal[17] among adolescent youth [10-17 years] in rural areas of Tamil Nadu in 2008 (combined prevalence of 5.1%), and by Reddy[18] among corporate schoolchildren [7-14 years] in Nellore, Andhra Pradesh in 2011 (combined prediabetes and diabetes prevalence of 9.5%) The present study showed an increasing prevalence of diabetes with increasing age with 2.2% prevalence of diabetes in the age group of 10-14 years, and 5% prevalence of diabetes in the age group of 15-19 years (p value=0.015). The increasing prevalence of diabetes in the present study could be attributed to urbanization, sedentary lifestyle, physical inactivity and presence of addictions like tobacco use and alcohol consumption.

The present study showed a significantly higher prevalence in subjects with a positive family history of diabetes (11.2%) as compared to those without positive family history of diabetes (2.4%, χ^2= 25.94, p value<0.001). In a multisite case-control study done in North India by Vikram et al[19] in 2006, it was found that a significantly higher number of cases had a history of type 2 diabetes in first-degree relatives as compared with controls [82.3% vs 23.2%, p value<0.001]. Anjana RM et al[20], in a community-based study on adolescents [12-19 years] in Chennai, detected that blood sugar levels were significantly higher in the group with two diabetic patients as compared to the groups with one diabetic parent, and no diabetic parents.

The present study showed an increasing prevalence of diabetes with increasing age with 2.2% prevalence of diabetes in the age group of 10-14 years, and 5% prevalence of diabetes in the age group of 15-19 years (p value=0.015).

The present study showed an increasing prevalence of diabetes with increasing body mass index (BMI), with 2.4% prevalence of diabetes in non-obese persons compared to 13.7% prevalence of diabetes in obese persons (χ^2= 30.63, p value<0.001). In a multisite case-control study conducted by Vikram et al[19] among adolescents and young adults in North India in 2006, it was observed that obesity was a risk factor for diabetes [OR=7.9(2.5-25.44)].

The present study showed that the prevalence of diabetes was significantly higher in adolescents who led a sedentary lifestyle (4.6%) as compared to those doing moderate work (1.9%, χ2= 5.25, p value 0.02). (Table 4) These findings are consistent with other studies done either in India or abroad. A multicentric study conducted by Mohan et al[21] in various parts of India from April 2003-March 2005 as part of the WHO-ICMR Indian NCD risk factor surveillance has found physical inactivity to be a strong risk factor for type 2 diabetes.

Conclusion and Recommendations:

Overall prevalence of diabetes was found to be 3.6%. Intensive IEC campaigns through multipronged strategies is needed to educate adolescents about diabetes, both in schools from primary level onwards as well as in communities, particularly focusing on – (1) prevention by recognition of important risk factors and lifestyle modifications (2) early diagnosis and treatment by recognition of symptoms.

Healthy lifestyle changes like change in food habits in terms of reduction of salty and fatty food, promotion of balanced diet complemented by regular exercise, weight reduction, etc. should be promoted through all strategies to reduce the prevalence of both diabetes.

Abstract:

Introduction: Adolescents constitute 20% of world's total population. Adolescents have become quite vulnerable to various non-communicable diseases (NCDs) like hypertension and diabetes mellitus, especially due to the tremendous changes in their lifestyle over the last few decades. The age of onset of Type 2 diabetes in India has been shifting towards ever younger people. Among Indians in their late teens [15-19 years], Type 2 diabetes already manifests itself more often than Type 1 diabetes does. **Objective:** To study prevalence and risk factors for Type 2 diabetes and pre diabetes among male and female adolescents in Udaipur city. **Method:** It was a Community based cross sectional study conducted in three urban areas of Udaipur for 6 months. A total of 1005 adolescents were included in the study. A pretested and predesigned questionnaire was used. **Results**: Prevalence of diabetes was 2.9% in males and 4.4% in females adolescents. Prevalence of smoking, alcoholism, non-vegetarian diet and hypertension was higher among males. **Conclusion:** Diabetes type 2 is a growing problem among adolescents. We need active involvement of health care workers for educating adolescents about risk factors for diabetes.

Key words: Adolescents, Diabetes, Pre-Diabetes.

Introduction:

According to the WHO, adolescence is defined as the period between 10 to 19 years, the second decade of life. This is a period of rapid growth and development for adolescents' bodies, minds and social relationships.[1] Adolescence is a process whereby an individual makes the gradual transition from childhood to adulthood and is a critical period of development, second only to the early childhood years. Adolescents constitute 20% of world's total population.[2]

According to 2011 Census of India, there are 253.2 million adolescents constituting 20.9% of the total population.[3] This number is ever increasing making it the largest generation to undergo transition from children to adults in the near future, in turn making India the youngest country of the world.

Adolescents have become quite vulnerable to various non-communicable diseases (NCDs) like hypertension and diabetes mellitus, especially due to the tremendous changes in their lifestyle over the last few decades. Over half of NCD related deaths are associated with behaviours that begin or are reinforced during adolescence, including tobacco and alcohol use, poor eating habits, and lack of exercise, compounded by the presence of obesity.[4]

Quick Response Code	Access this article online	How to cite this article :
	Website : www.healthlinejournal.org	Parmar M, Goyal G K, Gupta K, Chaudhary M. An Epidemiological Study to Assess Prevalence and Risk factors Associated with Diabetes Among Adolescents in Urban Areas of Udaipur. Healthline. 2021; 12 (1):22-28
	DOI : 10.51957/Healthline_170_2020	

Diabetes Mellitus (DM) is a chronic disorder characterized by raised blood sugar levels that occur when the pancreas does not produce enough insulin or when the body cannot effectively use the insulin it produces.[5] The International Diabetes Federation has estimated that about 382 million people all over the world suffer from diabetes. If these trends continue, by 2035, about 592 million people, or every tenth person, will have diabetes.[6] In India, the overall diabetes prevalence is 8%. Prevalence is only 0.7% for non-obese, physically active, rural Indians. It reaches 11% for obese, sedentary, urban Indians.[7] There are about 1 million juvenile diabetics in India, and every year 12000 diabetic children [2-14 years] die of the disease.[8]

Global and national estimates for the prevalence of diabetes in the adolescent age group are unavailable till date. In the United States, May et al found out that the combined prevalence of prediabetes & diabetes in American adolescents was 23% in 2007-2008.[9] The largest study in India was conducted by Singh et al among 10,843 adolescents in Chandigarh during the year 2007, and they detected a prevalence of diabetes of 4.2%.[10]

Although Type 1 diabetes is the most common form in children, Type 2 diabetes poses a major health problem globally, especially in the developing world. The age of onset of Type 2 diabetes in India has been shifting towards ever younger people. Among Indians in their late teens [15-19 years], Type 2 diabetes already manifests itself more often than Type 1 diabetes does.[11] Type 2 diabetes in children and adolescents is probably under-diagnosed because it can exist without symptoms. The clinical manifestations of T2DM are preceded by an asymptomatic prodromal period called 'prediabetes'.

Against the above background, the present study was carried out with the objective to study the prevalence of diabetes and associated risk factors among individuals in the age group 10-19 years in urban areas of Udaipur, Rajasthan.

Method:

Study Design : Community based cross sectional study.

Study Area : The study was conducted in three urban areas of Udaipur – Bhuwana [population 17660], Fatehpura [2 lakhs population] and Siphon [10000 population]. The three areas were selected as they are catered by the Department of Community Medicine of the medical college.

Study Period : Study was conducted for a period of 6 months from July 2019 to December 2019.

Study Subjects : Males and females of 10-19 years residing in these areas

Sample Size : At 95% confidence level and taking the prevalence of diabetes and prediabetes to be 9.5% with a relative error of 20%, the sample size came out to be 934 using the formula

$\mathbf{n = Z_\alpha^2\, p\, q\, /\, L^2}$,

Where n = sample size

Zα = 1.96 value of the standard normal variate corresponding to level of significance alpha 5 %

p = prevalence of diabetes[12], 9.5%

q = 100 – p, 90.5%

L = precision, 20%

Accounting for a non-response rate of 20%, a total of 1027 subjects were to be included. Out of these, 22 did not give consent to be part of the study, hence 1005 adolescents were included in the study. By simple random sampling, subjects were selected from the three areas. Proportionate probability sampling was followed.

Inclusion Criteria :

1. All males and females of 10-19 years after getting consent from them and informed written consent from their parents if they are <18 years, or after getting consent from them if they are 18 years or older.
2. The person should be a resident of the area mentioned above for a minimum of 6 months.

Study Instruments : A predesigned, pretested, semi-structured questionnaire containing items on (a) identification data i.e. age, gender, religion, educational status, area of residence, socioeconomic status of the person, (b) risk factor for diabetes i.e. obesity, sedentary lifestyle, smoking, alcohol, family history, dietary habits, history of consanguinity, etc. The questionnaire was pilot tested among 20 adolescents in the village of Delwara in June 2019, and questions were later modified to ensure that the subjects would have no difficulty in understanding and answering them. Glucometer, digital sphygmomanometer, measuring tape and weighing scale were used in the study. Following criteria were used.

Hypertension: The hypertension status of the study participants was assessed by using standard criteria formulated by the American Health Association (AHA) -2017.[13]

Diabetes criteria: Blood sugar determination (fasting) was done by glucometer by glucose oxidase

Table 1: Socio-demographic profile of study subjects

Characteristics	Total [n=1005]	
	Males [n=527] n (%)	Females [n=478] n (%)
Age (years)		
10-14	271 (51.4)	236 (49.4)
15-19	256 (48.6)	242 (50.6)
Religion		
Hindu	179 (33.9)	154 (32.2)
Muslim	326 (61.9)	306 (64)
Sikh	17 (3.2)	10 (2.1)
Christian	5 (1)	8 (1.7)
Education		
Illiterate	0	0
Primary/ Just literate	27 (5.1)	43 (8.9)
Middle School	198 (37.6)	182 (38.2)
High School	227 (43.1)	219 (45.8)
Intermediate/Diploma	75 (14.2)	34 (7.1)
Occupation		
Student	403 (76.5)	353 (73.9)
School dropout	22 (4.2)	80 (16.7)
Unskilled worker*	78 (14.8)	27 (5.7)
Semi-skilled worker**	24 (4.6)	18 (3.8)
Marital Status		
Married	12 (2.3)	56 (11.7)
Unmarried	515 (97.7)	422 (88.3)

*Unskilled worker: Person who are doing work which requires neither education nor specialized training.

**Semi-skilled worker: person who are doing work which requires some training to know their routine jobs efficiently.

method as per WHO and were interpreted. In the case of fasting plasma glucose (FPG) > 126mg /dl, a second determination was performed.[14]

Obesity criteria: Body mass index of the person was calculated using height and weight by applying the formula weight (in kgs) divided by square of height (in m^2).The cutoff criteria are based on the WHO BMI-for-age growth charts. Adolescents with BMI values at or above the 95th percentile of the sex-specific BMI growth charts are classified as obese.[15]

Ethical clearance and analysis: Institutional ethical clearance was taken. [No. AIMS/IEC/2019/022]. Statistical analysis was done using SPSS version 21.0.

Results:

Table 1 shows Majority of the subjects, 403 (76.5%) males and 353 (73.9%) females, were students. It was found that 22 (4.2%) males and 80 (16.7%) females were school dropouts and not doing anything. Out of 527 males, 24 (4.55%) and 78 (14.8%) were semi-skilled and unskilled workers respectively. It was also observed that, 12 (2.3%) males and 56 (11.7%) females were married, thereby highlighting the high prevalence of teenage marriage among adolescent girls. [Table 1]

Table 2 highlights that the prevalence of diabetes was 2.9% in males and 4.4% in females but the difference was not statistically significant (χ^2=3.66, p value 0.16)

Table 3 shows prevalence of smoking, alcoholism, non-vegetarian diet and hypertension was higher among males as compared to females. However, the difference was significant only for smoking (χ2=13.93, p value<0.001), alcoholism (χ2=36.76, p value<0.001) and non-vegetarian diet (χ2=4.51, p value 0.03).

Table 2 : Prevalence of diabetes among the study subjects

Classification of Diabetes	Males [n= 527] n (%)	Females [n=478] n (%)	Total [n=1005] n (%)	χ^2 value, d.f, p value
Normal	485 (92)	423 (88.5)	908 (90.4)	3.66, 2, 0.16

Table 4 highlights that subjects of 15-19 years age group experienced 2.03 times greater risk of getting diabetes as compared to subjects in the age group of 10-14 years (p value 0.02). Subjects who were obese experienced 1.86 times greater risk in comparison to those who were not obese (p value 0.05). Subjects with a positive family history of diabetes experienced 2.16 times greater risk of getting diabetes (p value 0.01). Subjects who led a sedentary lifestyle experienced 1.90 times greater risk of getting diabetes as compared to those engaged in moderate activity (p value 0.05). Subjects who were hypertensive experienced 1.79 times greater risk as compared to those who were not hypertensive (0.05).

Discussion:

The prevalence of diabetes in the present study was observed to be 3.6% among study subjects (2.9% in males and 4.4% in females) while the prevalence of prediabetes was observed to be 6.1% among the study subjects (5.1% in males and 7.1%

in females). Hence, the combined prevalence of diabetes and prediabetes among the study subjects was observed to be 9.7%. This was observed to be higher than that in the previous studies conducted by Ramachandran et al[16] among adolescents [12-19 years] in Chennai in 2007 (combined prediabetes and diabetes prevalence of 5.8%), by Singh et al[10] among 10,843 schoolgoing adolescents in Chandigarh in 2007 (4.2% prevalence of diabetes and 1.6% prevalence of prediabetes), by Balagopal[17] among adolescent youth [10-17 years] in rural areas of Tamil Nadu in 2008 (combined prevalence of 5.1%), and by Reddy[18] among corporate schoolchildren [7-14 years] in Nellore, Andhra Pradesh in 2011 (combined prediabetes and diabetes prevalence of 9.5%) The present study showed an increasing prevalence of diabetes with increasing age with 2.2% prevalence of diabetes in the age group of 10-14 years, and 5% prevalence of diabetes in the age group of 15-19 years (p value=0.015). The increasing prevalence of diabetes in the present study could be attributed to urbanization, sedentary lifestyle, physical inactivity and presence of addictions like tobacco use and alcohol consumption.

The present study showed a significantly higher prevalence in subjects with a positive family history of diabetes (11.2%) as compared to those without positive family history of diabetes (2.4%, χ^2= 25.94, p value<0.001). In a multisite case-control study done in North India by Vikram et al[19] in 2006, it was found that a significantly higher number of cases had a history of type 2 diabetes in first-degree relatives as compared with controls [82.3% vs 23.2%, p value<0.001]. Anjana RM et al[20], in a community-based study on adolescents [12-19 years] in Chennai, detected that blood sugar levels were significantly higher in the group with two diabetic patients as compared to the groups with one diabetic parent, and no diabetic parents.

The present study showed an increasing prevalence of diabetes with increasing age with 2.2% prevalence of diabetes in the age group of 10-14 years, and 5% prevalence of diabetes in the age group of 15-19 years (p value=0.015).

The present study showed an increasing prevalence of diabetes with increasing body mass index (BMI), with 2.4% prevalence of diabetes in non-obese persons compared to 13.7% prevalence of diabetes in obese persons (χ^2= 30.63, p value<0.001). In a multisite case-control study conducted by Vikram et al[19] among adolescents and young adults in North India in 2006, it was observed that obesity was a risk factor for diabetes [OR=7.9(2.5-25.44)].

The present study showed that the prevalence of diabetes was significantly higher in adolescents who led a sedentary lifestyle (4.6%) as compared to those doing moderate work (1.9%, χ2= 5.25, p value 0.02). (Table 4) These findings are consistent with other studies done either in India or abroad. A multicentric study conducted by Mohan et al[21] in various parts of India from April 2003-March 2005 as part of the WHO-ICMR Indian NCD risk factor surveillance has found physical inactivity to be a strong risk factor for type 2 diabetes.

Conclusion and Recommendations:

Overall prevalence of diabetes was found to be 3.6%. Intensive IEC campaigns through multipronged strategies is needed to educate adolescents about diabetes, both in schools from primary level onwards as well as in communities, particularly focusing on – (1) prevention by recognition of important risk factors and lifestyle modifications (2) early diagnosis and treatment by recognition of symptoms.

Healthy lifestyle changes like change in food habits in terms of reduction of salty and fatty food, promotion of balanced diet complemented by regular exercise, weight reduction, etc. should be promoted through all strategies to reduce the prevalence of both diabetes.

ABSTRACT

Background: Hypertension is the commonest cardiovascular disorder, posing a major public health challenge to population in socioeconomic and epidemiological transition. The objective of the study was to determine the prevalence of hypertension in the rural community.
Methods: Community-based cross sectional study was conducted in Chotkiram nagar village of Rupandehi district of Western Nepal. Door to door screening for hypertension was done using mercury sphygmomanometer. Other study variables included demographic factors only such as age and sex. The data was collected from 7th June 2016 to 20th June 2016. All the households in the village were screened and all the persons over 18 years of age in the households were subjected to blood pressure measurement. Thus the sample size comprised of all persons above 18 years of age. Total subjects enrolled were 3158. All persons above (and completed) 18 years of age and holding permanent resident status in the study area at the time of study were included in the study. Pregnant women and persons not willing to give consent were the exclusion criteria set. Though, all the participants gave their consent.
Results: The prevalence of hypertension in the study is 16.2%.
Conclusions: Though the hypertension is significant in the current study, the prevalence is much lower than the studies done in other parts of Nepal. More prevalence studies are required in the rural areas of Terai region.

Keywords: Screening, Hypertension, Prevalence, Rural

INTRODUCTION

Hypertension affects around 22% of people aged 18 years and over and is responsible for an estimated 9.4 million deaths per year globally.[1] It mostly remains asymptomatic but at the same time increases the risk of heart disease, stroke, and renal failure.[2] Hypertension is the commonest cardiovascular disorder, posing a major public health challenge to population in socioeconomic and epidemiological transition.[3]

Studies indicate that there is an epidemiological shift towards high prevalence of hypertension in developing countries as compared to developed countries.[4,5] Nepal is one such developing country where prevalence seems to increase.[6] However, more prevalence studies of hypertension are imperative to design preventive and control strategies. There are limited community based studies on hypertension in Nepal, very few in western regions. Hence, the present study done in Terai region of Western Nepal can also be considered as a baseline study in that geographical setting.

METHODS

This community-based cross sectional study was conducted in Chotkiram Nagar village of Rupandehi district of Western Nepal. This village is about 30 kms

from the city of Butwal. Geographically, Rupandehi is located in terai region of Nepal. The data was collected from 7th June 2016 to 20th June 2016. Door to door screening for hypertension was done using mercury sphygmomanometer. All the households in the village were screened and all the persons over 18 years of age in the households were subjected to blood pressure measurement. The total participants were 3158 from 880 households of the village having population of 4879.

Other study variables included demographic factors only such as age and sex. All persons above (and completed) 18 years of age and holding permanent resident status in the study area at the time of study were included. Pregnant women and persons not willing to give consent were the exclusion criteria set. Though, all the participants gave their consent. Ethical clearance was taken and written permission was obtained from Village Development Committee Office (VDC), Chotkiram nagar.

The purpose of visit was explained to the family members and consent taken. For this study, Joint National Committee (JNC-7) guideline for diagnosis of hypertension was used (SBP ≥140 mmHg and/or DBP ≥ 90 mmHg).[7] Persons on anti-hypertensive medications were considered hypertensive. Persons with isolated systolic hypertension were considered hypertensive and included in the study. The data collected was entered in the excel sheet of the computer. Statistical analysis included calculation of percentages and proportions.

RESULTS

Description of the study population

Total number of subjects enrolled were 3158. Out of which, males were 1648 (52.2%) and females were 1510 (47.8%). Around 59% of the population belonged to age group less than 35 years.

Table 1: Demographic characteristics of the study population.

Variable	Number (%)
Sex	
Male	1648 (52.2)
Female	1510 (47.8)
Age group	
18-25	938 (29.7)
26-35	916 (29)
35-45	566 (17.9)
46-55	364 (11.5)
55+	374 (11.8)

The total prevalence of hypertension was found to be 16.2%. Prevalence among males was 17.5% and in females was 14.8%.

Table 2: Prevalence of hypertension.

Sex	Total no.	Hypertensive	Prevalence (%)
Male	1648	289	17.5
Female	1510	223	14.8
Total	3158	513	16.2

DISCUSSION

Screening is a fundamental aspect of prevention. It is active search for disease among apparently healthy people. Hypertension is a disease which fulfills the criteria to be considered suitable for screening. Moreover, it is a major public health problem. It is particularly a health menace to society in socioeconomic and epidemiological transition. To plan an effective preventive and control strategy one need to quantify the health problem. Nepal is a geographically diversified country divided into Terai (plain), Hilly and Himal regions. Studies have been conducted to know the prevalence of hypertension in hilly regions and some in Himal regions but very few in Terai regions. In the current community based survey in terai region of western Nepal on subjects 18 years and above of age, the prevalence of hypertension was found to be 16.2%

A study done in 2011 by Chataut et al in Central Nepal in rural area among adults above 18 years revealed the prevalence of hypertension to be 22.4%.[8] Vaidya et al in a study at Kathmandu urban in 2006 reported the prevalence to be 33.8%.[6] The WHO STEPs surveillance conducted in 2007 in Nepal reported the prevalence to be 31.3%.[9] While Sharma et al in 2011 in a study in eastern Nepal concluded it to be 33.9%.[10] Prevalence of hypertension in the current study (16.2%) is lower than the prevalence studies done in past in Nepal. Though, the prevalence of our study is much closer to findings reported by Sharma et al in suburban areas of Kathmandu in 2005. [11] They reported the prevalence to be 19.7%. The study conducted by Lamsal and Kafle in Himal region (high hilly areas) of Nepal reported the prevalence of hypertension to be 35.7%. 214 out of total 600 subjects enrolled were found to be hypertensive in their study. They suggest that the higher prevalence of hypertension may be due to certain behavioral patterns prevailing in the area. They further opined that, higher consumption of locally made alcohol, using yak butter and salt in tea, higher rates of smoking and poor availability of fruits and vegetables may have role.[12] To the best of our knowledge and extensive review of literature we did not find prevalence studies on hypertension in Western Nepal especially the Terai region. So we were not able to compare our study findings with other studies of Western region. However, a cross-sectional study conducted by Khan et al among adult women in Terai region of Central Nepal revealed the prevalence to be 3.3%. One likely explanation of the lower prevalence was given to the young age of participants in the study by the authors.

Though, the prevalence among 46 years and above age group was 7.9% in their study. [13]

Additionally, the findings of our study are much closer to the prevalence of hypertension reported in rural areas of North India and West India. A meta-analysis study on prevalence of hypertension in India by Anchala et al in 2013 reported that the pooled prevalence of hypertension for rural North Indian population was 14.5% while for the rural West Indian population was 18.1%.[14] Alcohol, smoking and chewing tobacco, central obesity, consumption of low vegetables and fruits, high consumption of dietary fat and salt, sedentary activity were the significant modifiable risk factors for hypertension among the Indians as per this study.[14]

CONCLUSION

The prevalence of hypertension is 16.2%. Though hypertension is emerging as health concerns, in-depth study is required pertaining to the risk factors of hypertension among people to understand the reasons of lower prevalence in our study setting. More studies are also required in the rural areas of Terai region of Nepal to corroborate the findings.

ACKNOWLEDGEMENTS

The author acknowledges the support of Village Development Committee (VDC) office, Chotkiram nagar, Rupandehi for the study.

Abstract
Background: Three tier system exists in India. The upper most is the CHC. The CHC provides specialist services to the rural people and is usually located at the block level. The CHCs are under constant criticism for their inability to deliver quality services. The main reasons are the lack of proper manpower, inadequate infrastructure. In order to provide optimal level of quality health care, a set of standards called IPHS were submitted. In the above context, the present study was undertaken with the objective to assess the infrastructure facilities & availability of manpower in the CHCs of Ahmedabad district, Gujarat.
Method and Materials: Study was carried out from April 2014 to December 2015. It is Cross-sectional study. Predesigned and pretested questionnaire made from IPHS revised guideline 2012. It was planned to study at least 2/3rd (70%) of the existing means CHCs i.e. 7 CHCs. So, it was randomly selected 7 CHCs by chit method.
Result: 100% CHCs had building but only 57.14% CHCs had male female separate wards and toilets. 100% CHCs had OT and Labour room, but only 28.57% CHCs had Blood storage facility and none of the CHCs had USG facility. The availability of medical staff and support manpower was also poor. 100% CHCs had done Pathological tests. X-ray were done in 71.42% CHCs and ECG were done in 28.57% CHCs.
Conclusion: Pooling of human resources needs to be done especially Specialists and promoting partnership with the private sector in providing human resources. There is need to be strengthen physical infrastructure like male:female separate wards and toilets, investigation facility.

Keywords: IPHS, CHC, manpower, physical infrastructure

1. Introduction
The National Rural Health Mission (NRHM) was launched by the Hon'ble Prime Minister of India in the year of 2005 with the goal of improving the availability and accessibility of the quality health care to the people, especially for those residing in rural areas, the poor, and women [1, 2]. Right now, the three tier system exists in all over country in India in rural area [1, 3]. The sub centres are the first (lower most) tier of this system. The second one is primary health centre and the upper most is the community health centre.[3]. The Community Health Centre provides specialist services to the rural people and is usually located at the block level [4, 5].
Standards are a means of describing the level of quality that Health care organizations are expected to meet or aspire to. Key aim of these standards is to underpin the delivery of quality services. The performance of health care delivery organizations can be assessed against standards [6].
In order to provide optimal level of quality health care, a set of standards called Indian Public Health Standards (IPHS) were submitted the draft guidelines for "Indian Public Health Standards for CHCs in 2006 which was then revised in 2007, 2010 and 2012. IPHS is a novel concept to fix benchmarks of infrastructure, including building, manpower, equipments, drugs, quality, through introduction of treatment protocols, and accountability to the public. The study is to evaluate the functioning of the CHCs of Ahmedabad District and their effectiveness in bringing specialised health care within the reach of rural people [7].
The CHCs are under constant criticism for their inability to deliver quality services. The main reasons are the lack of proper manpower, inadequate infrastructure and facilities. In the above context, the present study was undertaken with the objective to assess the infrastructure facilities & availability of manpower in the CHCs of Ahmedabad district, Gujarat.

2. Materials and Methods
The present study was conducted in CHCs of Ahmedabad district. Study was carried out from April 2014 to December 2015. It is Cross-sectional study. Predesigned and pretested questionnaire made from IPHS revised guideline 2012 was used for the study. There were 10 CHCs in Ahmedabad district. List of all the CHCs were obtained from the Jilla Panchayat, Ahmedabad. It was planned to study at least 2/3rd (70%) of the existing means CHCs i.e. 7 CHCs. So, it was randomly selected 7 CHCs by chit method. Before conducting the study, prior permission of Chief District Health Officer, Superintendent and Medical officers respectively of CHCs was taken. For the quality assessment of the facilities at CHCs the observational and interview methods were used. Check list was prepared as per the standard of the IPHS. The respondents of the study were the persons in charge of the health facility. However, in some of the facilities, the person in charge was not available hence, another officer was interviewed

3. Result and Discussion

Table 1: Availability of physical infrastructure facilities at CHCs in Ahmedabad

Infrastructure facilities	Availability of Infrastructure facilities (7)	
	Number of CHCs	Percentage of CHCs (%)
Building	7	100.00
OPD rooms/cubicles	7	100.00
Waiting room	3	42.85

The present study revealed that 100% CHCs had E-mail facility and only 28.57 % CHCs had Fax facility. Similar study conducted at Bharatpur district, Rajasthan by P.R. Sodani *et al*. (2010) [7], showed that 84.6% CHCs had E-mail and 76.9% CHCs had Fax facility. In present study 100% CHCs had Operation theatre, Labour room, Laboratory and Cold chain facility. Similar finding were observed in study conducted by P.R. Sodani *et al*. (2010) [7], showed that 100 % CHCs had Operation theatre, Laboratory and cold chain facility, while 92.3 % CHCs had Labour room. Study done by Jayanta B Sarma *et al*., (2011) [8] shows, In Arunachal Pradesh 79.16% CHCs had functional Laboratory and 77.08% had functional OT 95.83% had functional Labour room, while in case of Assam 100% CHCs had laboratory and Labour room and 93.51% CHCs had functional OT.

In this 28.57 % CHCs had General surgeon, Physician and Anaesthetist, while 71.42 % CHCs had OBG and 57.14 % CHCs had Paediatrician.100 % MBBS Medical Officer and 42.85 % AYUSH present at all 7 CHCs. Study by P.R. Sodani *et al*. (2010) [7], also shows that 30.8% surgeon and paediatrician, while 38.5 % Physician and OBG available at CHCs, while only 41% medical officers present at CHCs, which were contradictory to our findings. Study by Jayanta B Sarma *et al*., (2011) [8] shows that none of the CHCs in Arunachal Pradesh had all 4 specialist, while in Assam 25.92% had all 4 specialist.

In present study 68.57 % Staff nurse, 100 % Pharmacist available, while 57.14% Lab technician and 71.14% Radiographer available. Study by P.R. Sodani *et al*. (2010) [7], also showed poor availability of human resources. Study revealed only 78.4% Staff nurse, 30.8 % Pharmacist, 66.7% Lab technician and only 50% Radiographer available, which were lower than present study.

In present study 100 % CHCs had Pathological tests facility, while 71.42% had X-ray facility and only 28.57% CHCs had ECG facility. Similar consistence findings were observed in study by P.R. Sodani *et al*. (2010) [7], 100% CHCs had Pathological tests facility, while 69.2% CHCs had X-ray facility and only 23% CHCs had ECG facility.

4. Conclusion

100% CHCs had building but only 57.14% CHCs had male female separate wards and toilets. 100% CHCs had OT and Labour room, but only 28.57% CHCs had Blood storage facility and none of the CHCs had USG facility.

The availability of specialists to provide various specialist services at CHCs was found to be very poor in the study district. However it was observed that there were recommended number of MBBS MO present at PHCs, while only 42.85% AYUSH MO were present.

The availability of support manpower was also poor, but found to be better at the participating CHCs compared to the specialists. 100% CHCs had done Pathological tests. X-ray were done in 71.42% CHCs and ECG were done in 28.57% CHCs. Pooling of human resources needs to be done especially Specialists and promoting partnership with the private sector in providing human resources. There is need to be strengthen physical infrastructure like male: female separate wards and toilets, investigation facility.

Assistant Professor, Department of Community Medicine, AIMS & RC, Rajsamand, India

Received: 08-07-2020 / Revised: 07-09-2020 / Accepted: 20-09-2020

Abstract

The current scenario depicts that immunization coverage has been steadily increasing but the average level remains far less than the desired. Though there is increased accessibility of health care services in rural areas, its utilization is low. Hence the present study is undertaken in an attempt to assess immunization status of children enrolled in anganwadi centers .Each Anganwadi centre was considered as a single cluster and all children from the selected anganwadi centers were included in the study. Data was analyzed. The major cause of incomplete immunization was postponement of immunization due to inter current illness of the child. There is only marginal difference in immunization coverage according to gender, education of parents. Regular health education sessions, and regular reminders and removal of misconceptions prevailing among people will solve the problems of non-immunization.

Keywords: non immunization,anganwadi

Introduction

Vaccine preventable diseases are widespread and a major cause of childhood morbidity, mortality and life-long physical disability.Immunization has been one of the most significant and cost-effective public-health interventions to decrease childhood morbidity and mortality[1].Universal Immunization Programme was started in India in 1985 with the aim to achieve 100% coverage of pregnant woman with 2 doses of tetanus toxoid(or a booster dose) and at least 85% coverage of infants with 3 doses each of DPT,OPV; one dose of BCG and one dose of measles by 1990.

Aims & objectives

•To assess immunization status among beneficiaries of anganwadies.

•To identify the reasons for partial/ non immunization among them.

•To know the impact of sex, cast, mother's education on the immunization status of the registered children of anganwadi[2-4].

Methodology

•Study design: Cross sectional study

•Study area: Anganwadies of field practice area of AIMS & RC, Rajsamand

•Study method & sample:Registered beneficiaries of anganwadies were included in study[5-7].

5 anganwadies were randomly selected. 206 children (registered children of anganwadi>1 year of age),19 antenatal women and 56 adolescent girls(registered adolescent girls >16 years of age) were included in study.

Children, their mothers and other beneficiaries were asked to remain present on the anganwadi Centre on the days of our visit and information was collected from them & from anganwadi registers in pre designed proforma.

Data analysis: Data was entered in MS Excel and analyzed by using simple proportions and chi-square test[8,9].

Results & observations

Children: Of the 206 children, 180(87.38%) were found fully immunized &26(12.62%) were found partially immunized. None of them were found non-immunized.Coverage for individual vaccines were found as – 100% for BCG; 99.02%,96.6% and 95.14%

for OPV 1,OPV 2 and OPV 3 respectively; 98.54%,96.6% and 94.66% for DPT 1,DPT 2 and DPT 3 respectively while 89.8% for measles.The coverage of pulse polio immunization was 98.54%.

Antenatal women: Coverage for TT was found 100%. **Adolescent girls:** Only 14(25%) adolescent girls had taken complete two doses of TT.

Table 2: Association between education status and availability of immunization card

Education status of mother	Immunization card available	Immunization card not available	Total
≥Primary	88(78.57%)	24(21.43%)	112(54.37%)
< Primary	54(57.45%)	40(42.55%)	94(45.63%)
Total	142(68.93%)	64(31.07%)	206(100%)

X^2=10.649 ; p<0.05

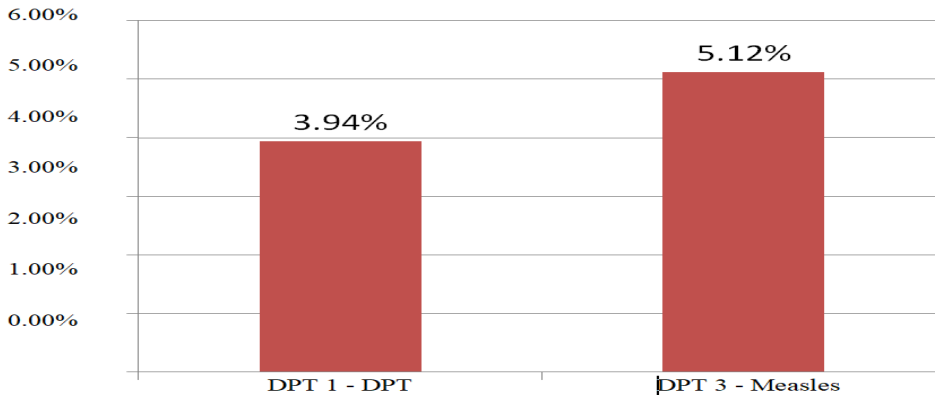

Fig 3: Drop-out rate among children

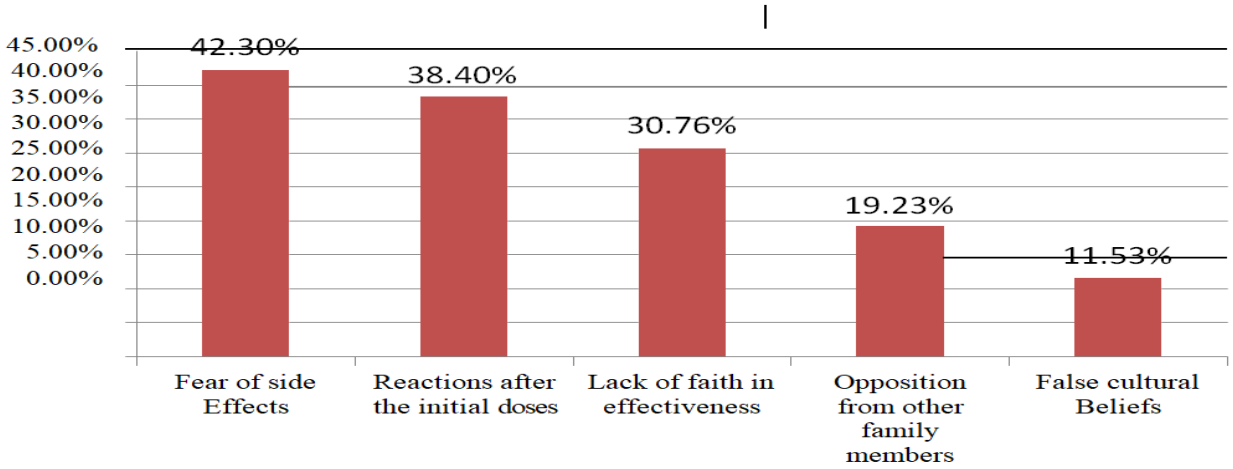

Fig 4:Reasons for partial immunization among children

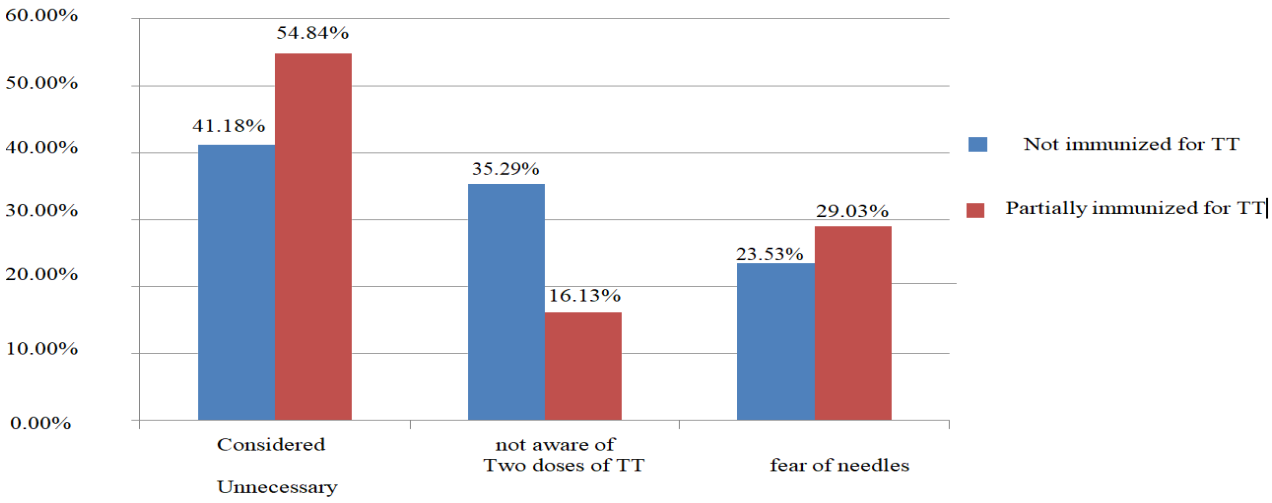

Fig 5: Reasons for Partial/Non- immunization among adolescents

Conclusion

•From the present study it is concluded that ICDS has played very successful role in increasing the immunization status of antenatal women and children.
•Immunization for Tetanus Toxoid among the adolescent girls was found low, so the need of an hour is to raise awareness among them.
•Timely health education should be provided to the mothers regarding the importance , schedule, common side effects and efficacy of the vaccines.
•Minor reactions following the injectable vaccines should be minimized.
•Interest should be developed both in local health functionaries and adolescent beneficiaries to accelerate the optimization of immunization among the adolescent girls.

ABSTRACT

Background: Psychosocial impact of obesity is of concern in the present world but remains less studied compared to its physical consequences. People who take treatment for obesity are reported to be positively associated with psychiatric illnesses and also personality characteristics or psychological conditions influence the obesity treatment. **Objective:** The objective of this study was to study the prevalence of psychiatric illness and comorbid conditions among people with overweight and obesity and to find out factors associated with psychiatric illness. **Materials and Methods:** A cross-sectional study was conducted in private obesity clinic, Ahmedabad. A total of 103 people attending obesity clinic were studied. Self-structured questionnaire and Hospital Anxiety and Depression Scale (HADS) were used. **Results:** Of 103, 87.5% (91) were female. Mean age of people attending obesity clinic was 35 ± 9.2 years. About 67.3% were housewife and 92.2% were educated up to secondary or above. Thirty-eight (38.8%) and 59 (57.2%) of 103 were found to be having overweight and obesity, respectively. About 69% of people with obesity belong to Grade 1 and 31% belong to Grade 2 and 3. Psychiatric illness was observed among 38.8% (40) of the obesity clinic attendees. Of 40, 32.5% were found to have abnormal level of HADS score and needed intervention. Of 103, 45.6% had comorbid conditions such as joint associated problems (25%), hypertension (16.5%), and hypothyroidism (14%). Among overweight and obese with comorbidities, 48.9% had psychiatric illness. Psychiatric illness was observed among 37% of people with duration of obesity >5 years. The study did not find any significant association between overweight and obese having comorbid conditions ($z = 0.63$, $P > 0.05$) and duration of obesity ($z = 0.44$, $P > 0.05$) with psychiatric illness. **Conclusion:** Both comorbidity and psychiatric illness are highly prevalent among obese people. This indicates early detection and intervention for both to decrease the morbidity and mortality among obese and overweight.

KEY WORDS: Obesity; Comorbidities; Psychiatric Illness; Hospital Anxiety and Depression Scale Score

INTRODUCTION

Obesity, across all age groups and cultures it is the most prevalent global public health problem. Obesity in recent times is referred to as "New World Syndrome," since it causes many non-communicable diseases creating large sums of socioeconomic and public health problems in developing countries. Affecting every age group, it is the most undermined health problem in accordance of the WHO.[1]

Previously, due to high prevalence of undernutrition in developing countries, including India, had limited public health resources mainly on dealing with it. However, these developing countries are now dealing with double burden of undernutrition as well as overnutrition. Body mass index (BMI) is the indicator of nourishment status in adults. The studies regarding BMI indicate that 50% of Indian adults suffer from various types of chronic energy deficiency

Access this article online	
Website: http://www.ijmsph.com	Quick Response code
DOI: 10.5455/ijmsph.2018.0413126042018	

in that they have a BMI <18.5 kg/m^2. In the same survey, it was observed that the BMI values were similar in men and women; however, there were more overweight/obese (BMI ≥25 kg/m^2) women (6.6%) than men (3.5%). In certain parts of the country, obesity and consequent diseases are posing a huge public health problem.[2]

We now know that the biggest global health burden for the world is related to diet and this burden is enhanced by relation with low physical activity. At present, roughly, 300 million adults worldwide are obese – a BMI of 30 and above, nearly 1 billion people are overweight. The problem affects apparently all age groups and in every socioeconomic status.[2]

Obesity statistics has risen at least 3 times since the late 20th century in Western nations. In most of the developing countries, obesity and malnutrition are coexisting in all socioeconomic strata. The growing problem is due to adoption of industrialized foods and food preferences, together with drastically decreased physical activity levels. It may trigger psychological problems that include depression, eating disorders, distorted body image, and low self-esteem. Higher rates of depression have been found in obese people in several studies. Evidence from the Swedish obese subjects study indicates that clinically significant depression is 3–4 times higher in severely obese individuals than in similar non-obese individuals. Professor Marianne Sullivan *et al.* from Sahlgrenska University Hospital, Sweden, mentioned in a journal article, "depression on a level indicating psychiatric morbidity was more often seen in the obese." The study suggests that levels of depression among obese were more or less same as chronic pain.[2]

In the developing countries, the high obesity statistics is due to change in diet and decrease in physical activity; it is known as the "nutrition transition." In Urban populations, there are higher rates of obesity as compared to rural populations. Urban areas offer a variety of food, generally at lower costs and urban population usually have less physical activity as compared to rural population.[2]

At different levels of BMI, there is difference in fat deposition and body composition. Overweight cutoffs of 25 are not applicable for Asian population, the burden is greater these populations. This resulted in the prevalence of diabetes, impaired fasting glucose and hypertension in Asians.[3]

In near future, the developing countries will suffer greater burden due to obesity. In the first quarter of the 21st century, diabetes due to obesity estimates is to be doubled in world, of which roughly three-fourth burden will be on developing countries.[4]

People with a BMI more than 30 are more likely to be diagnosed with hypertension, stroke, high cholesterol, coronary heart disease (CHD), osteoarthritis, gout, asthma, sleep disorders dermatological problems, and some types of cancer as compared to adults with normal weight.

The American Heart Association in 1998 declared that obesity is major risk factor for CHD. Obesity plays a causal role in the development of type 2 diabetes mellitus and its complication, due to which treatment of diabetes becomes less yielding.[5]

The inconsistent results found in various studies and with an increase concern about the psychological effects of overweight and obesity along with associated comorbidities warrant more research in this field. Most of the available data are from the Western world that may not be relevant in the Asian region. To address this issue, we conducted a study to investigate the prevalence of morbidity due to psychiatric disorders among obese individuals.

Objectives

The objectives of this study were to study the prevalence of psychiatric illness and other comorbid conditions among the people with overweight and obesity and to find out the factors associated with psychiatric illness among obese visiting obesity clinic.

MATERIALS AND METHODS

This study was conducted in private obesity clinic, Ahmedabad. This was a cross-sectional study performed from September 2017 to November 2017.

All the obese person attending the clinic for 3 months were included, so a total of 103 obese people attended the clinic were studied. Data were obtained using a self-administered questionnaire consisting of general information, comorbid conditions and its treatment, awareness about obesity, and Hospital Anxiety and Depression Scale score (HADS) which consist of 14 questions. Scoring was done separately for anxiety and depression, any score in between 0 and 7 considered normal, 8–10 borderline case, and 11–21 abnormal case. BMI was calculated using weight/height^2 and classified according to the WHO Asian BMI classification.[6]

Data analysis was done using Microsoft Excel 2007. For statistical analysis, Chi-square test was applied. Verbal consent was taken from all respondents.

RESULTS

Of 103, 87.5% (91) were female. Mean age of people attending obesity clinic was 35 ± 9.2 years. About 67.3% were housewife and majority (92.2%) were educated up to secondary or above [Table 1].

Thirty-eight (38.8%) and 59 (57.2%) of 103 were found to be having overweight and obesity, respectively. About 69% of people with obesity belong to Grade 1 and 31% belong to Grade 2 and 3. Nearly 40% of the attendees have a history of obesity in <5 years. The study did not find a statistically significant association between overweight and obese having duration of obesity >5 or <5 years with psychiatric illness ($z = 0.44$, $P > 0.05$). Due to small number of male participants, gender-specific comparison was not done [Table 2].

About 45.6% had comorbid conditions such as joint associated problems (25%), hypertension (16.5%), and hypothyroidism (14%). The study did not find a statistically significant association between overweight and obese having psychiatric disorder with comorbid conditions ($z = 0.63$, $P > 0.05$) [Figure 1].

Abnormal HADS score was observed among 38.8% (40) of the obesity clinic attendees. Of 40, 32.5% were found to have psychiatric illness and needed intervention [Table 3].

DISCUSSION

In the 21st century, obesity is becoming an epidemic in different regions of South Asia including India. Unique features of obesity; abdominal adiposity, high body fat, intra-abdominal fat, and high amount of subcutaneous fat are exhibited by Asian Indians.[7] Individuals who are obese tend to have more emotional problems resulting in various psychosocial and health-related issues. We retrospectively questioned 103 patients who received variety of obesity treatments. In our study, 87.5% were female, as female preponderance of obesity was observed in other studies as well. This pattern of attendees may be due to some sociocultural reason. Similar observation was made by the study at Taiwan.[8] Most of the respondents belonged to adult age group, 68% were housewife and had a better economic and educational status when compared to other studies.[8] Obesity is found to be one of the primary conditions to result in various comorbidities. In this study, 46% were having some comorbid conditions such as joint associated problems, hypertension, and hypothyroidism, and they were at ongoing treatment. In general, it is difficult to explain the potential association of comorbidities with a psychiatric disorder among the obese subjects with the available scientific evidence.[9,10] Our study also did not find a statistically significant association between overweight and obese having psychiatric disorder with comorbid conditions ($z = 0.63$, $P > 0.05$). Psychological stress is found to be more in women due to stigma of overweight and obesity, dissatisfactory thoughts for their body image, and haphazard eating habits.[11] In a community-based survey, it was found that obese females suffer from more chance of depression and anxiety.[12] The patients were evaluated on the basis of standardized questionnaire and HADS score. Abnormal level of HADS was observed among 38.8% (40) of the obesity clinic attendees and majority needed intervention. Similar prevalence was seen in another study carried out in Kerala,[9] at least one psychiatric disorder was seen in 42% of patients in a study conducted in Taiwan.[8]

Increased weight in psychiatric disorder patients involves the number and duration of depressive episodes, history of hospital admissions for depression, medicines causing increase in weight, decrease in physical activity,[13] comorbid anxiety disorders, and age.[12] About 40% of the patients reported within 5 years of weight gain, it shows their awareness of health and it was interfering with their day-to-day work, so

Table 1: Sociodemographic distribution of obesity clinic attendees

Sex	Frequency (%)
Male	12 (11)
Female	91 (87.5)
Age	
<20	04 (3.8)

Table 3: Number of attendees with their HADS score

HADS score	Depression	Anxiety
Normal (0–7)	88	69
Borderline abnormal (8–10)	12	21
Abnormal/case (11–21)	3	13

Psychiatric illness was observed among 38.8% (40) of the obesity clinic attendees. Of 40, 32.5% were found to have abnormal level of HADS score and needed intervention. HADS: Hospital anxiety and depression scale

most of the patients were counseled for preventive measures such as diet, exercise, yoga, and walking.

Several intensive steps are required in obese patients that include medication according to metabolic profile of patients, treatment for weight loss, lifestyle modifications, and counseling for managing weight so that management can be sustained.[12,13] Depression causes low-energy level and motivation, leading person to care less about their health and causes change in their appetite. Our study found that the association was statistically not significant between obese and duration of obesity >5 or <5 years with psychiatric illness ($z = 0.44$, $P > 0.05$).

However, the meta-analytical study, it was found that the relationship between obesity and depression is bidirectional. Studies suggest that depressed people have a 58% increased chance of becoming obese, whereas obese people have 55% more chance of becoming depressed overtime.[10] Difference in our study may be due to smaller sample size. Further evaluation is required to find out possible cause of the association between depression and obesity; it may be psychological and biological.

CONCLUSION

The study showed considerable rate of psychiatric disorder in obese and overweight patients. This indicates early detection and intervention needed for both to decrease the morbidity and mortality among overweight and obese and also needed for a multidisciplinary approach in the management of obesity. Further study is required to prove that psychiatric evaluation might play an important role in completing obesity treatment. Actions need to be taken at different levels of organizations, multimedia, and educational institutions along with some changes in food distribution and policies.

In certain parts of the country, obesity and consequent diseases are posing a huge public health problem.[2]

We now know that the biggest global health burden for the world is related to diet and this burden is enhanced by relation with low physical activity. At present, roughly, 300 million adults worldwide are obese – a BMI of 30 and above, nearly 1 billion people are overweight. The problem affects apparently all age groups and in every socioeconomic status.[2]

Obesity statistics has risen at least 3 times since the late 20th century in Western nations. In most of the developing countries, obesity and malnutrition are coexisting in all socioeconomic strata. The growing problem is due to adoption of industrialized foods and food preferences, together with drastically decreased physical activity levels. It may trigger psychological problems that include depression, eating disorders, distorted body image, and low self-esteem. Higher rates of depression have been found in obese people in several studies. Evidence from the Swedish obese subjects study indicates that clinically significant depression is 3–4 times higher in severely obese individuals than in similar non-obese individuals. Professor Marianne Sullivan *et al.* from Sahlgrenska University Hospital, Sweden, mentioned in a journal article, "depression on a level indicating psychiatric morbidity was more often seen in the obese." The study suggests that levels of depression among obese were more or less same as chronic pain.[2]

In the developing countries, the high obesity statistics is due to change in diet and decrease in physical activity; it is known as the "nutrition transition." In Urban populations, there are higher rates of obesity as compared to rural populations. Urban areas offer a variety of food, generally at lower costs and urban population usually have less physical activity as compared to rural population.[2]

At different levels of BMI, there is difference in fat deposition and body composition. Overweight cutoffs of 25 are not applicable for Asian population, the burden is greater these populations. This resulted in the prevalence of diabetes, impaired fasting glucose and hypertension in Asians.[3]

In near future, the developing countries will suffer greater burden due to obesity. In the first quarter of the 21st century, diabetes due to obesity estimates is to be doubled in world, of which roughly three-fourth burden will be on developing countries.[4]

People with a BMI more than 30 are more likely to be diagnosed with hypertension, stroke, high cholesterol, coronary heart disease (CHD), osteoarthritis, gout, asthma, sleep disorders dermatological problems, and some types of cancer as compared to adults with normal weight.

The American Heart Association in 1998 declared that obesity is major risk factor for CHD. Obesity plays a causal role in the development of type 2 diabetes mellitus and its complication, due to which treatment of diabetes becomes less yielding.[5]

The inconsistent results found in various studies and with an increase concern about the psychological effects of overweight and obesity along with associated comorbidities warrant more research in this field. Most of the available data are from the Western world that may not be relevant in the Asian region. To address this issue, we conducted a study to investigate the prevalence of morbidity due to psychiatric disorders among obese individuals.

Objectives

The objectives of this study were to study the prevalence of psychiatric illness and other comorbid conditions among the people with overweight and obesity and to find out the factors associated with psychiatric illness among obese visiting obesity clinic.

MATERIALS AND METHODS

This study was conducted in private obesity clinic, Ahmedabad. This was a cross-sectional study performed from September 2017 to November 2017.

All the obese person attending the clinic for 3 months were included, so a total of 103 obese people attended the clinic were studied. Data were obtained using a self-administered questionnaire consisting of general information, comorbid conditions and its treatment, awareness about obesity, and Hospital Anxiety and Depression Scale score (HADS) which consist of 14 questions. Scoring was done separately for anxiety and depression, any score in between 0 and 7 considered normal, 8–10 borderline case, and 11–21 abnormal case. BMI was calculated using weight/height^2 and classified according to the WHO Asian BMI classification.[6]

Data analysis was done using Microsoft Excel 2007. For statistical analysis, Chi-square test was applied. Verbal consent was taken from all respondents.

RESULTS

Of 103, 87.5% (91) were female. Mean age of people attending obesity clinic was 35 ± 9.2 years. About 67.3% were housewife and majority (92.2%) were educated up to secondary or above [Table 1].

Thirty-eight (38.8%) and 59 (57.2%) of 103 were found to be having overweight and obesity, respectively. About 69% of people with obesity belong to Grade 1 and 31% belong to Grade 2 and 3. Nearly 40% of the attendees have a history of obesity in <5 years. The study did not find a statistically significant association between overweight and obese having duration of obesity >5 or <5 years with psychiatric illness ($z = 0.44$, $P > 0.05$). Due to small number of male participants, gender-specific comparison was not done [Table 2].

About 45.6% had comorbid conditions such as joint associated problems (25%), hypertension (16.5%), and hypothyroidism (14%). The study did not find a statistically significant association between overweight and obese having psychiatric disorder with comorbid conditions ($z = 0.63$, $P > 0.05$) [Figure 1].

Abnormal HADS score was observed among 38.8% (40) of the obesity clinic attendees. Of 40, 32.5% were found to have psychiatric illness and needed intervention [Table 3].

DISCUSSION

In the 21st century, obesity is becoming an epidemic in different regions of South Asia including India. Unique features of obesity; abdominal adiposity, high body fat, intra-abdominal fat, and high amount of subcutaneous fat are exhibited by Asian Indians.[7] Individuals who are obese tend to have more emotional problems resulting in various psychosocial and health-related issues. We retrospectively questioned 103 patients who received variety of obesity treatments. In our study, 87.5% were female, as female preponderance of obesity was observed in other studies as well. This pattern of attendees may be due to some sociocultural reason. Similar observation was made by the study at Taiwan.[8] Most of the respondents belonged to adult age group, 68% were housewife and had a better economic and educational status when compared to other studies.[8] Obesity is found to be one of the primary conditions to result in various comorbidities. In this study, 46% were having some comorbid conditions such as joint associated problems, hypertension, and hypothyroidism, and they were at ongoing treatment. In general, it is difficult to explain the potential association of comorbidities with a psychiatric disorder among the obese subjects with the available scientific evidence.[9,10] Our study also did not find a statistically significant association between overweight and obese having psychiatric disorder with comorbid conditions ($z = 0.63$, $P > 0.05$). Psychological stress is found to be more in women due to stigma of overweight and obesity, dissatisfactory thoughts for their body image, and haphazard eating habits.[11] In a community-based survey, it was found that obese females suffer from more chance of depression and anxiety.[12] The patients were evaluated on the basis of standardized questionnaire and HADS score. Abnormal level of HADS was observed among 38.8% (40) of the obesity clinic attendees and majority needed intervention. Similar prevalence was seen in another study carried out in Kerala,[9] at least one psychiatric disorder was seen in 42% of patients in a study conducted in Taiwan.[8]

Increased weight in psychiatric disorder patients involves the number and duration of depressive episodes, history of hospital admissions for depression, medicines causing increase in weight, decrease in physical activity,[13] comorbid anxiety disorders, and age.[12] About 40% of the patients reported within 5 years of weight gain, it shows their awareness of health and it was interfering with their day-to-day work, so

Table 1: Sociodemographic distribution of obesity clinic attendees

Sex	Frequency (%)
Male	12 (11)
Female	91 (87.5)
Age	
<20	04 (3.8)
20–29	31 (29.8)
30–39	39 (37.8)
40–49	24 (23.0)
>50	05 (4.8)
Occupation	
Working	23 (22.1)
Housewife	70 (67.3)
Student	10 (9.61)

Illiterate	01 (0.9)
Primary	07 (6.7)
Secondary and Higher secondary	48 (46.6)
Graduate and PG	47 (45.6)

Table 2: Classification of attendees according to BMI and years of obesity

Obese classification	BMI (kg/m^2)	Frequency
Normal	18.5–25	04
At risk of overweight (2–20 years)	85–95%	01
Overweight	25–30	40 (38.8%)
Obese Class 1	30–35	40
Obese Class 2	35–40	09
Obese Class 3	>40	09
Obese since (years)	Number of person	%
<5	41	39.8
5–10	28	27.1
10–15	13	12.6
>15	21	20.3

BMI: Body mass index

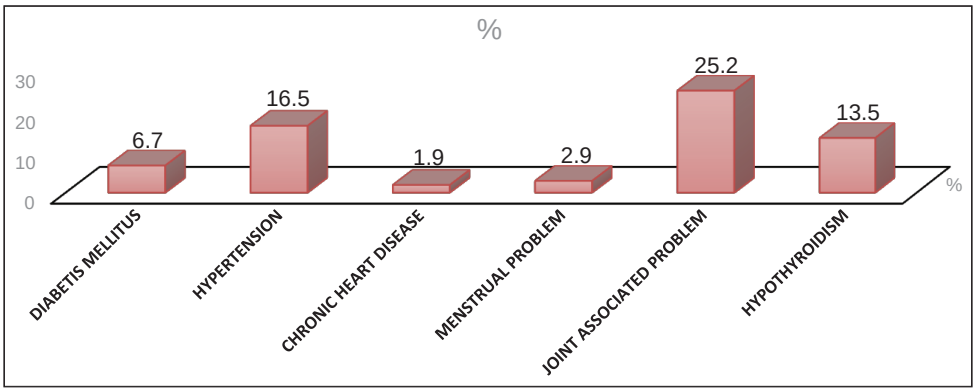

Figure 1: Number of patients (%) with comorbid conditions (Total = 47 [45.6%])

Table 3: Number of attendees with their HADS score

HADS score	Depression	Anxiety
Normal (0–7)	88	69
Borderline abnormal (8–10)	12	21
Abnormal/case (11–21)	3	13

Psychiatric illness was observed among 38.8% (40) of the obesity clinic attendees. Of 40, 32.5% were found to have abnormal level of HADS score and needed intervention. HADS: Hospital anxiety and depression scale

most of the patients were counseled for preventive measures such as diet, exercise, yoga, and walking.

Several intensive steps are required in obese patients that include medication according to metabolic profile of patients, treatment for weight loss, lifestyle modifications, and counseling for managing weight so that management can be sustained.[12,13] Depression causes low-energy level and motivation, leading person to care less about their health and causes change in their appetite. Our study found that the association was statistically not significant between obese and duration of obesity >5 or <5 years with psychiatric illness ($z = 0.44$, $P > 0.05$).

However, the meta-analytical study, it was found that the relationship between obesity and depression is bidirectional. Studies suggest that depressed people have a 58% increased chance of becoming obese, whereas obese people have 55% more chance of becoming depressed overtime.[10] Difference in our study may be due to smaller sample size. Further evaluation is required to find out possible cause of the association between depression and obesity; it may be psychological and biological.

CONCLUSION

The study showed considerable rate of psychiatric disorder in obese and overweight patients. This indicates early detection and intervention needed for both to decrease the morbidity and mortality among overweight and obese and also needed for a multidisciplinary approach in the management of obesity. Further study is required to prove that psychiatric evaluation might play an important role in completing obesity treatment. Actions need to be taken at different levels of organizations, multimedia, and educational institutions along with some changes in food distribution and policies.

ABSTRACT

Background: B12 deficiency is extremely common in India. Deficiency has varied manifestations and causes a range of disorders such as anemia, gastrointestinal, and neuropsychiatric manifestation and affects all age groups. **Objectives:** The aim of the study is to assess the clinical and sociodemographic variables associated with Vitamin B12 deficiency among symptomatic patients and to correlate the symptoms with serum level of Vitamin B12 deficiency. **Materials and Methods:** A cross-sectional observational study carried out among 97 patients attending fever outpatient department at civil hospital, Ahmedabad. Patients were interviewed with pretested questionnaire and were subjected for biochemical estimation of Vitamin B12, mean corpuscular volume, and hemoglobin. **Results:** Median age of attendees was 25 years (range: 13–64). Three out of eight symptoms were weakness (96.9%), tingling and numbness in hand and feet (60.8%), and fatigue (57.7%). All the patients who were tested on the basis of symptoms were found to be having Vitamin B12 insufficiency (<300 pg/ml). 46.3% were having severe deficiency (<150 pg/ml). Out of severely Vitamin B12 deficient patient, 47.8% were having any type of anemia. Study did not find any significant association ($P < 0.05$) between gender, diet, water supply, and level of Vitamin B12, whereas there was a significant association between religion and severity of Vitamin B12 deficiency ($\chi^2 = 6.09$, $P < 0.05$). **Conclusion:** All the patients need to be clinically screened for symptoms of B12 deficiency, and even the mild symptomatic patients should be treated to prevent the severe form of deficiency or neuropsychiatric manifestations. This will also reduce the unnecessary burden on laboratory.

KEY WORDS: Vitamin B12; Deficiency; Age; Religion

INTRODUCTION

Vitamin B12 is water-soluble vitamin, which is present in some foods naturally, added to some food items, and it is available as a prescription supplement in oral and injectable forms. Mineral "cobalt" is present in all the different forms of Vitamin B12, and therefore, these compounds with Vitamin B12 functions are called as "cobalamins." In our metabolism, two chemical forms of Vitamin B12, i.e., methylcobalamin and 5-deoxyadenosylcobalamin are active. Functions of Vitamin B12 in the human body include neurological development, synthesis of genetic material, i.e., DNA and maturation of red blood cells and other activity such as working as a cofactor for certain enzymes such as L-methylmalonyl-CoA mutase and methionine synthase.[1]

The assessment of Vitamin B12 status is done by serum Vitamin B12 levels. For adults, values <170–250 pg/mL (120–180 pmol/L) are considered Vitamin B12 deficiency. [1] People with Vitamin B12 deficiency show various

DOI: 10.5455/ijmsph.2019.0721530072019	

symptoms which are often ignored, and chronic deficiency leads to neurological impairment and anemia. Therefore, prompt treatment is warranted if deficiency is found in serum Vitamin B12 levels.[2]

Neurological problems due to deficiency of Vitamin B12 include paresthesia, memory loss, ataxia, vision problem, and peripheral neuropathy. Another major effect of Vitamin B12 deficiency is due to immature red blood cells leading to megaloblastic anemia. There is a type of megaloblastic anemia called pernicious anemia caused by autoimmune mechanism; in this type of anemia, intrinsic factor (IF) of castle is destroyed by autoimmunity which is essential in the absorption of Vitamin B12 and this also increases the risk of development of stomach cancer. Vitamin B12 deficiency in the antenatal period is responsible for the neural tube defect in fetus. The deficiency also causes temporary infertility which is rare and usually improves by treating with Vitamin B12.[3]

Among the causes of Vitamin B12 deficiency, autoimmune pernicious anemia is the most common cause. Some other common causes include ileal resection, gastrectomy, pancreatic insufficiency, and malabsorption syndromes. Some less common causes include the use of drugs such as biguanides, antacids, aminoglycoside antibiotics, colchicine, and rarely malabsorption due to gastrointestinal overgrowth of bacterial and parasitic infestation. Pure nutritional deficiency is rare and usually occurs only in strict vegans.[4]

In case of specific populations, deficiency proportion is highest among pregnant women which is often associated with folate deficiency leading to developmental defects in fetus. Deficiency rates are reported to be higher in vegans than vegetarians. Among vegetarians, higher deficiency rates are seen in people vegetarian since birth compared to people who became vegetarian later in life.[5]

Early recognition of symptoms and prompt treatment has shown beneficial effect in case of serious neurological symptoms. Other than paresthesia and optic atrophy, rest all neurological symptoms are reversible if treated early.[6]

B12 deficiency is extremely common. There are many reasons for this and are related to diet, lifestyle, social, and cultural issues. In spite of being a common disorder, its recognition is delayed or missed because the manifestations are diverse in nature, affecting all the organs and systems, and is often subclinical. To add to the confusion, laboratory estimations are notoriously unreliable even from the best of centers and doctors tend to rely on laboratory estimate of B12 levels.

The present study is aimed to assess the clinical and sociodemographic variables associated with Vitamin B12 deficiency among symptomatic patients and to correlate symptoms with serum Vitamin B12 level.

MATERIALS AND METHODS

A cross-sectional study was done in fever outpatient department (OPD) of civil hospital, Asarwa, Ahmedabad. All the symptomatic patients attending fever OPD during period of September 2017–November 2017 were interviewed with pretested structured questionnaire, and those who were found positive for three symptoms out of eight, i.e., weakness, fatigue, tingling and numbness in hands and feet, soreness in mouth, poor memory and depressive symptoms, constipation, weight loss, and loss of appetite were subjected for biochemical estimation of Vitamin B12, mean corpuscular volume (MCV), and hemoglobin. Analysis was done using Microsoft Excel 2007 and Chi-square test. Ethical permission was taken. Informed consent was taken from patient after explaining about the study.

RESULTS

Table 1 shows sociodemographic distribution of patients attending the fever OPD. Out of total 97 patients, 70 were females (72%) and 27 (28%) were males. Median age of attendees was 25 years (range: 13–64).

Figure 1 shows complaints of symptoms among OPD attendees. It was found that most patients complaining of weakness (96.9%), tingling and numbness in hands and feet (60.8%), and fatigue (57.7%).

Hb: Hemoglobin

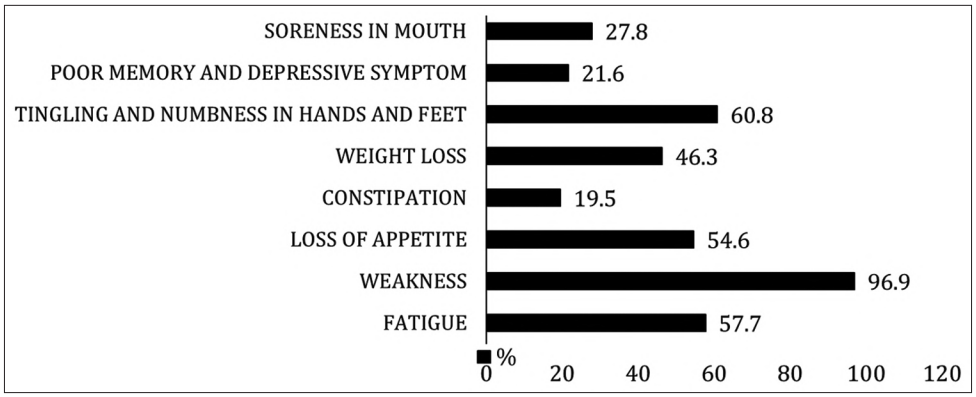

Figure 1: Complaints of symptoms among patients attending outpatient department

Figure 2 shows hemoglobin level in patients with Vitamin B12 deficiency. All the patients who were tested on the basis of symptom were found to be having Vitamin B12 insufficiency (<300 pg/ml) as per laboratory reports. Out of severely Vitamin B12 deficient patient, 47.8% were having any type of anemia.

Table 2 shows relation between sociodemographic variables and Vitamin B12 deficiency. Study did not find any significant association ($P > 0.05$) between gender, diet, water supply, and level of Vitamin B12, whereas there was a significant association between religion and severity of Vitamin B12 deficiency ($\chi^2 = 6.09$, $P < 0.05$).

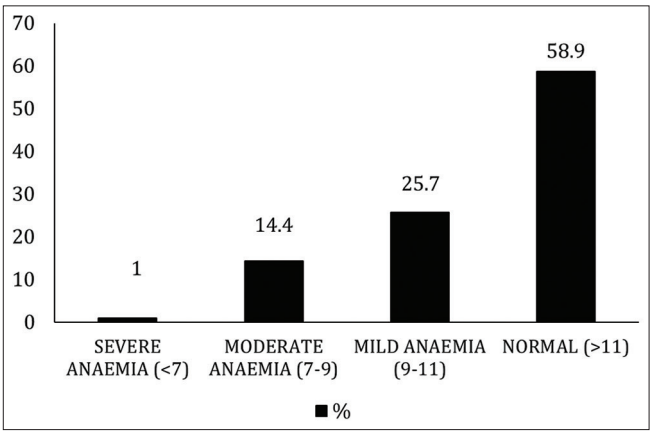

Figure 2: Hemoglobin level in patients with Vitamin B12 deficiency patients

DISCUSSION

Vitamin B12 deficiency is frequently underdiagnosed and undertreated condition due to vague symptoms which leads to chronic deficiency and irreversible neurological impairments. Therefore, clinical assessment and serology both are very important for diagnosis.[2]

This study shows that the median age of attendees was 25 years, and the number of males was not enough to make any gender-based conclusion whereas in some studies done on south Asians risk appeared to be similar for male and female.[7] Majority of the patients were vegetarian (63.9%), the deficiency even among patients who were non-vegetarian, it was found that they ate meat only occasionally. They were using municipality water supply (86.5%) and belong to lower socioeconomic class (63.8%). However, our study did not find any significant association ($P > 0.05$) between gender, diet, water supply, and Vitamin B12 deficiency. There was a significant association between religion and severity of Vitamin B12 deficiency ($\chi^2 = 6.09$, $P < 0.05$) which may be due to difference in cultural practices. Similar study done in Toronto found Vitamin B12 deficiency even among non-vegetarians.[7] Most common symptoms were weakness,

tingling and numbness in hands and feet, and fatigue which is similar to study conducted in Maharashtra.[8] All patients who were tested on the basis of symptoms (n = 97) were having Vitamin B12 deficiency of which 46.3% were having severe deficiency (<150 pg/ml), 36% were having deficiency (150–200 pg/ml), whereas 17.7% were having potential undersupply (200–300 pg/ml).[9] There is evidence that B12 deficiency might clinically present at a much higher B12 concentration, i.e., in low normal range (500–600 pg/ml). Lindenbaum *et al*. observed that many individuals presented with deficiency symptoms at serum Vitamin B12 levels as high as 350 pg/ml,[10] whereas in another group, Van Tiggelen *et al*. recommended levels to be 600 pg/ml.[11] Our study shows that 61.8% of patients had normal range of MCV, which tell us that MCV alone is not enough as a diagnostic parameter of Vitamin B12 deficiency. Out of Vitamin B12 deficient patient (n = 97), 47.8% were having any type of anemia because of the often coexisting iron deficiency could decrease MCV levels. Similar findings were seen in a study done in Toronto in south Asians.[7]

In our study, there were limitations, we did not use any other biochemical markers, for example, methyl-malonic acid or homocysteine; this study was based on serum B12 results and clinical symptoms, which alone, without other biochemical markers might be inaccurate measures of B12 deficiency. Outside our study setting, i.e., tertiary level of health facility, these findings might not be generalized.

Strength for this study as patients were available in fever clinic and agreed to take part in the study, so study was conducted easily.

Recommendations

On the basis of this study, it is recommended that medical graduate and postgraduate should be trained in such a way to rely on clinical skill to make a clinical judgment rather than laboratory investigation to initiate therapy. Advocate a diet plan to give benefit to the patient. Serum B12 levels <100 pg/ml are reported to have specificity approaching 90% for diagnosing clinically manifested Vitamin B12 deficiency. Hence, patients with low Vitamin B12 level should be further tested for methylmalonic acid and IF antibodies.

CONCLUSION

Since study observed that majority had severe form of B12 deficiency, all the patients need to be clinically screened for symptoms of B12 deficiency and even the mild symptomatic patients should be treated to prevent the severe form of deficiency or neuropsychiatric manifestations. This will also reduce the unnecessary burden on laboratory.

All the patients who were tested on the basis of symptoms were found to be having Vitamin B12 insufficiency (<300 pg/ml). 46.3% were having severe deficiency (<150 pg/ml). Out of severely Vitamin B12 deficient patient, 47.8% were having any type of anemia. Study did not find any significant association ($P < 0.05$) between gender, diet, water supply, and level of Vitamin B12, whereas there was a significant association between religion and severity of Vitamin B12 deficiency ($\chi^2 = 6.09$, $P < 0.05$). **Conclusion:** All the patients need to be clinically screened for symptoms of B12 deficiency, and even the mild symptomatic patients should be treated to prevent the severe form of deficiency or neuropsychiatric manifestations. This will also reduce the unnecessary burden on laboratory.

KEY WORDS: Vitamin B12; Deficiency; Age; Religion

INTRODUCTION

Vitamin B12 is water-soluble vitamin, which is present in some foods naturally, added to some food items, and it is available as a prescription supplement in oral and injectable forms. Mineral "cobalt" is present in all the different forms of Vitamin B12, and therefore, these compounds with Vitamin B12 functions are called as "cobalamins." In our metabolism, two chemical forms of Vitamin B12, i.e., methylcobalamin and 5-deoxyadenosylcobalamin are active. Functions of Vitamin B12 in the human body include neurological development, synthesis of genetic material, i.e., DNA and maturation of red blood cells and other activity such as working as a cofactor for certain enzymes such as L-methylmalonyl-CoA mutase and methionine synthase.[1]

The assessment of Vitamin B12 status is done by serum Vitamin B12 levels. For adults, values <170–250 pg/mL (120–180 pmol/L) are considered Vitamin B12 deficiency. [1] People with Vitamin B12 deficiency show various

DOI: 10.5455/ijmsph.2019.0721530072019	

symptoms which are often ignored, and chronic deficiency leads to neurological impairment and anemia. Therefore, prompt treatment is warranted if deficiency is found in serum Vitamin B12 levels.[2]

Neurological problems due to deficiency of Vitamin B12 include paresthesia, memory loss, ataxia, vision problem, and peripheral neuropathy. Another major effect of Vitamin B12 deficiency is due to immature red blood cells leading to megaloblastic anemia. There is a type of megaloblastic anemia called pernicious anemia caused by autoimmune mechanism; in this type of anemia, intrinsic factor (IF) of castle is destroyed by autoimmunity which is essential in the absorption of Vitamin B12 and this also increases the risk of development of stomach cancer. Vitamin B12 deficiency in the antenatal period is responsible for the neural tube defect in fetus. The deficiency also causes temporary infertility which is rare and usually improves by treating with Vitamin B12.[3]

Among the causes of Vitamin B12 deficiency, autoimmune pernicious anemia is the most common cause. Some other common causes include ileal resection, gastrectomy, pancreatic insufficiency, and malabsorption syndromes. Some less common causes include the use of drugs such as biguanides, antacids, aminoglycoside antibiotics, colchicine, and rarely malabsorption due to gastrointestinal overgrowth of bacterial and parasitic infestation. Pure nutritional deficiency is rare and usually occurs only in strict vegans.[4]

In case of specific populations, deficiency proportion is highest among pregnant women which is often associated with folate deficiency leading to developmental defects in fetus. Deficiency rates are reported to be higher in vegans than vegetarians. Among vegetarians, higher deficiency rates are seen in people vegetarian since birth compared to people who became vegetarian later in life.[5]

Early recognition of symptoms and prompt treatment has shown beneficial effect in case of serious neurological symptoms. Other than paresthesia and optic atrophy, rest all neurological symptoms are reversible if treated early.[6]

B12 deficiency is extremely common. There are many reasons for this and are related to diet, lifestyle, social, and cultural issues. In spite of being a common disorder, its recognition is delayed or missed because the manifestations are diverse in nature, affecting all the organs and systems, and is often subclinical. To add to the confusion, laboratory estimations are notoriously unreliable even from the best of centers and doctors tend to rely on laboratory estimate of B12 levels.

The present study is aimed to assess the clinical and sociodemographic variables associated with Vitamin B12 deficiency among symptomatic patients and to correlate symptoms with serum Vitamin B12 level.

MATERIALS AND METHODS

A cross-sectional study was done in fever outpatient department (OPD) of civil hospital, Asarwa, Ahmedabad. All the symptomatic patients attending fever OPD during period of September 2017–November 2017 were interviewed with pretested structured questionnaire, and those who were found positive for three symptoms out of eight, i.e., weakness, fatigue, tingling and numbness in hands and feet, soreness in mouth, poor memory and depressive symptoms, constipation, weight loss, and loss of appetite were subjected for biochemical estimation of Vitamin B12, mean corpuscular volume (MCV), and hemoglobin. Analysis was done using Microsoft Excel 2007 and Chi-square test. Ethical permission was taken. Informed consent was taken from patient after explaining about the study.

RESULTS

Table 1 shows sociodemographic distribution of patients attending the fever OPD. Out of total 97 patients, 70 were females (72%) and 27 (28%) were males. Median age of attendees was 25 years (range: 13–64).

Figure 1 shows complaints of symptoms among OPD attendees. It was found that most patients complaining of weakness (96.9%), tingling and numbness in hands and feet (60.8%), and fatigue (57.7%).

Table 1: Sociodemographic distribution of patients

Parameters	Frequency (*n*=97)	Percentage

Hb: Hemoglobin

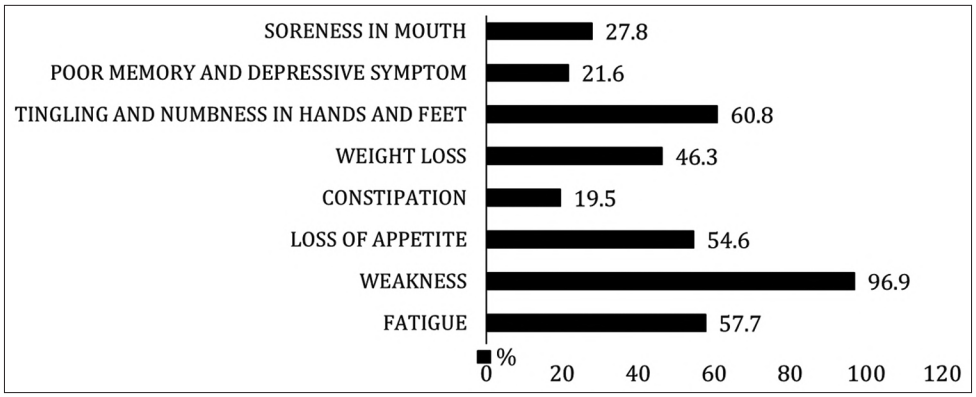

Figure 1: Complaints of symptoms among patients attending outpatient department

Figure 2 shows hemoglobin level in patients with Vitamin B12 deficiency. All the patients who were tested on the basis of symptom were found to be having Vitamin B12 insufficiency (<300 pg/ml) as per laboratory reports. Out of severely Vitamin B12 deficient patient, 47.8% were having any type of anemia.

Table 2 shows relation between sociodemographic variables and Vitamin B12 deficiency. Study did not find any significant association ($P > 0.05$) between gender, diet, water supply, and level of Vitamin B12, whereas there was a significant association between religion and severity of Vitamin B12 deficiency ($\chi^2 = 6.09$, $P < 0.05$).

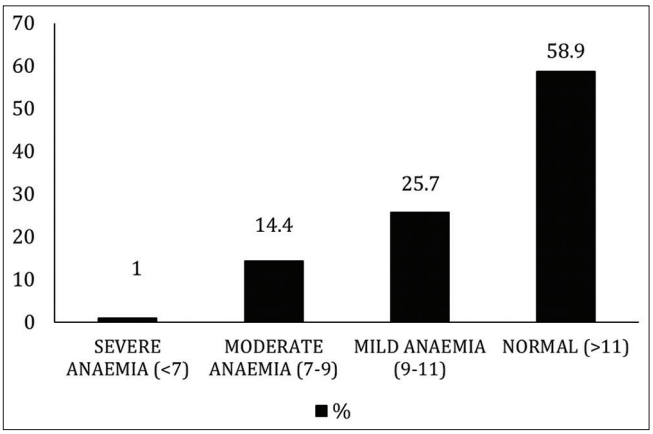

Figure 2: Hemoglobin level in patients with Vitamin B12 deficiency patients

DISCUSSION

Vitamin B12 deficiency is frequently underdiagnosed and undertreated condition due to vague symptoms which leads to chronic deficiency and irreversible neurological impairments. Therefore, clinical assessment and serology both are very important for diagnosis.[2]

This study shows that the median age of attendees was 25 years, and the number of males was not enough to make any gender-based conclusion whereas in some studies done on south Asians risk appeared to be similar for male and female.[7] Majority of the patients were vegetarian (63.9%), the deficiency even among patients who were non-vegetarian, it was found that they ate meat only occasionally. They were using municipality water supply (86.5%) and belong to lower socioeconomic class (63.8%). However, our study did not find any significant association ($P > 0.05$) between gender, diet, water supply, and Vitamin B12 deficiency. There was a significant association between religion and severity of Vitamin B12 deficiency ($\chi^2 = 6.09$, $P < 0.05$) which may be due to difference in cultural practices. Similar study done in Toronto found Vitamin B12 deficiency even among non-vegetarians.[7] Most common symptoms were weakness,

tingling and numbness in hands and feet, and fatigue which is similar to study conducted in Maharashtra.[8] All patients who were tested on the basis of symptoms (n = 97) were having Vitamin B12 deficiency of which 46.3% were having severe deficiency (<150 pg/ml), 36% were having deficiency (150–200 pg/ml), whereas 17.7% were having potential undersupply (200–300 pg/ml).[9] There is evidence that B12 deficiency might clinically present at a much higher B12 concentration, i.e., in low normal range (500–600 pg/ml). Lindenbaum *et al*. observed that many individuals presented with deficiency symptoms at serum Vitamin B12 levels as high as 350 pg/ml,[10] whereas in another group, Van Tiggelen *et al*. recommended levels to be 600 pg/ml.[11] Our study shows that 61.8% of patients had normal range of MCV, which tell us that MCV alone is not enough as a diagnostic parameter of Vitamin B12 deficiency. Out of Vitamin B12 deficient patient (n = 97), 47.8% were having any type of anemia because of the often coexisting iron deficiency could decrease MCV levels. Similar findings were seen in a study done in Toronto in south Asians.[7]

In our study, there were limitations, we did not use any other biochemical markers, for example, methyl-malonic acid or homocysteine; this study was based on serum B12 results and clinical symptoms, which alone, without other biochemical markers might be inaccurate measures of B12 deficiency. Outside our study setting, i.e., tertiary level of health facility, these findings might not be generalized.

Strength for this study as patients were available in fever clinic and agreed to take part in the study, so study was conducted easily.

Recommendations

On the basis of this study, it is recommended that medical graduate and postgraduate should be trained in such a way to rely on clinical skill to make a clinical judgment rather than laboratory investigation to initiate therapy. Advocate a diet plan to give benefit to the patient. Serum B12 levels <100 pg/ml are reported to have specificity approaching 90% for diagnosing clinically manifested Vitamin B12 deficiency. Hence, patients with low Vitamin B12 level should be further tested for methylmalonic acid and IF antibodies.

CONCLUSION

Since study observed that majority had severe form of B12 deficiency, all the patients need to be clinically screened for symptoms of B12 deficiency and even the mild symptomatic patients should be treated to prevent the severe form of deficiency or neuropsychiatric manifestations. This will also reduce the unnecessary burden on laboratory.

ABSTRACT

Background: Indian Diabetes Risk Score [IDRS] by Madras Diabetic Research Foundation was approved as screening tool in National programme for prevention and control of Cancer, Diabetes, Cardiovascular Diseases and Stroke (NPCDCS). This study was planned to test the utility of IDRS in screening diabetes among urban population. **Methods:** This cross-sectional study was conducted among 625 individuals residing in urban wards of Rajahmundry in 2013-14. Data was collected on socio-demographic variables, anthropometric measurements followed by testing for fasting blood sugars to diagnose diabetes. Area under receiver operating characteristic curve was calculated for presence of diabetes. **Results:** In the present study 49.92% population had high risk score (≥60) for diabetes. The prevalence of diabetes in our study was about 15.4%, and pre-diabetes was 4.5 % (total 19.9%). It was observed that obesity among females was 43.36%, among males it was 31.52%. In this study IDRS >60 had the sensitivity of 79.17% and specificity of 50.0%. IDRS >60 not only diagnoses diabetes also identifies coronary artery disease. In the community it also helps to identify metabolic syndrome.

Conclusions: IDRS is a useful screening tool for early diagnosis diabetes and initiation of appropriate lifestyle interventions to prevent various complications of diabetes mellitus.

Key Words: Diabetes mellitus, Indian Diabetes Risk Score, urban adults, Andhra Pradesh

INTRODUCTION

Diabetes Mellitus is the most common non communicable disease globally with more than 424.9 million people.[1] China having highest burden of diabetes with 114.4 million, India is in second position with 72.9 million.[2] India is expected to emerge as a global leader in diabetes mellitus by the year 2045. Even though India is having huge burden of diabetes in the world, most of them remain undiagnosed.[3] Early detection is critical for moderating the health and economic impacts of the disease. It is neither feasible nor cost effective to perform universal screening for type 2 diabetes using blood sugar estimations to cover the whole population. Targeted screening with a non-invasive test for initial selection of subjects followed by plasma glucose testing in high risk individuals only is a more efficient approach.[3] Assessment of risk of undiagnosed type 2 diabetes is commonly used to identify individuals who need to be recommended for further biochemical testing.

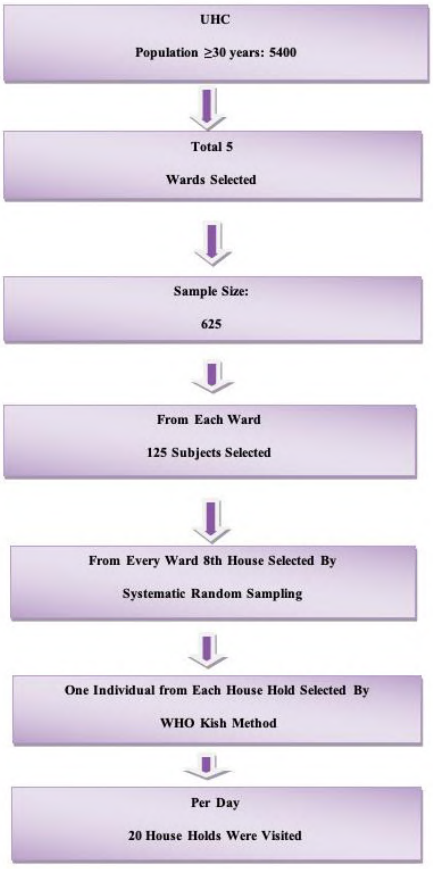
Diabetes is not only disease of affluence now it is increasing in slum areas. The increasing risk factors are like taking junk foods, high calorie and high cholesterol diets, sedentary life styles, smoking and alcohol habits.[4] This vulnerable population because of unawareness, inaccessibility to health care, health seeking behaviour also less among urban slums need interventions that are cost effective, feasible for screening and detection of diabetes and early signs of complications.[5] To detect millions of Indians by Indian Diabetes Risk Score [IDRS], which is cost effective, feasible, non-invasive and non bio-chemical Madras Diabetic Research Foundation was approved by Government of India and utilised as screening tool in National programme for prevention and control of cancer, Diabetes, Cardiovascular Diseases and stroke (NPCDCS).[6] Keeping in view of afore mentioned facts, study was carried out in the urban health centre area of a Medical College to test the utility of Indian diabetic risk score in screening diabetes among urban population.

MATERIAL AND METHODS

This study was commenced after institutional ethical committee approval. Written informed consent was obtained from respondents. The study was conducted at urban wards of Rajahmundry city in Andhra Pradesh, over a period of one year. The prevalence of known diabetes in urban areas according to ICMR is around 14-20%. The prevalence of type-2 diabetes in these areas is 13.5% at 95% confidence interval with 80% power, the expected sample size required to estimate the prevalence of diabetes was 625. The type of probability sampling adopted for this study is multistage sampling technique for selecting wards and households (Figure 1).

Data collection was done using a pretested questionnaire containing details of socio-demographic profile (Age, sex, income, education, occupation, and religion), anthropometric variables (height, weight, waist circumference and clinical details for each study participant, risk was assessed using an IDRS scoring. Fasting capillary blood glucose was determined using the glucose meter (One Touch Ultra, Life scan Johnson & Johnson) to those subjects with IDRS score >60. According to ADA guidelines fasting capillary blood >126 is diagnostic of diabetes. ADA recommended use of fasting blood glucose alone for diagnosis in epidemiological studies as well as in clinical diagnosis except in pregnant.[7] All newly diagnosed diabetic subjects were asked to confirm their diabetes with a venous OGTT or repeat plasma glucose values at the local urban health centre or at a government hospital.

Figure 1. PROCEDURE OF CONDUCTION OF STUDY



Definitions:

Diabetes: Diabetes was defined by physician diagnosis of diabetes and current use of medications for diabetes (insulin or oral hypoglycaemic agents) and/or fulfilment of criteria laid down by the WHO Consultation Group Report, i.e., capillary fasting blood glucose ≥126 mg/dl or 2 h capillary post-glucose value ≥220 mg/dl.[8]

Impaired Fasting Glucose: Impaired fasting glucose was defined based on WHO criteria, i.e., if fasting capillary blood glucose ≥110 and <126 mg/dl.[8]

Impaired Glucose Tolerance: Impaired glucose tolerance was defined according to WHO criteria where 2hr capillary post-glucose value is ≥160 but <220 mg/dl with a fasting value in the non diabetic range. All data collected were stored electronically. All statistical analyses were performed by using SPSS Software version-21 for Windows, MedCalc. Version 12.7.3.0. Software for Windows and Ms-excel 2007. Values were presented as Mean ± SD and in percentages. Chi-square tests were used for examining the association of categorical variables. Binary logistic regression was used for predicting the diabetes. For all statistical analyses $p<0.05$ was considered statistically significant. ROC curves were drawn for validating IDRS Scores.

RESULTS

Table-1: Descriptive Statistics of the Baseline characteristics (N=625)

Study Variables	Min.	Max.	Mean	Std. Deviation

	≥126	-	96 (100)	96 (77.42)	
Total		5 (4.03)	119 (95.97)	124	

Table-4: Correlations between IDRS Abdominal Obesity & FBS (n=312)

Study Variables		IDRS Abdominal Obesity	FBS
IDRS Abdominal Obesity	Pearson Correlation	1	0.142*
	Significance (2-tailed)	-	0.012
FBS	Pearson Correlation	0.142*	1
	Significance (2-tailed)	0.012	-

*Correlation is significant at the 0.05 level (2-tailed)

with IDRS total >60 (n=312). It was observed that among 312 subjects, 96 of them got fasting blood sugar >126mg/dl.

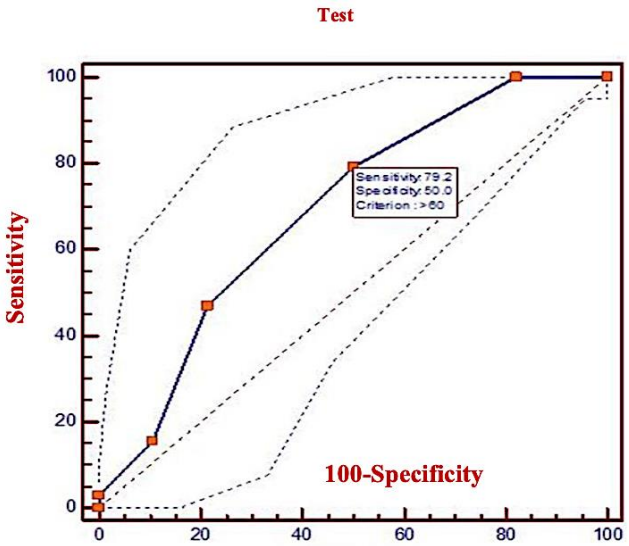
Descriptive statistics of continuous variables shows mean age of participants in this study is 42.85±10.574, mean systolic BP of the participants is 136.97 ± 23.929, mean diastolic BP is 86.99±17.762, mean weight is 66.14±9.062 which are in the hypertensive range and obese ranges. Mean IDRS total in this study is 52.74% nearer to mainly pre diabetic range. Mean cooking oil usage per person is 0.8597 kg which is higher than recommended daily usage per person i.e., 0.5 kg per person per month. Mean waist and waist hip ratios are showing on higher ranges. (Table 1)

Table-5: Linear Regression between IDRS Abdominal Obesity & FBS (n=312)

Model	Unstandardized Coefficients		Standardized Coefficients		Signifi-cance
	B	Std. Error	Beta	t	
(Constant)	97.743	2.76	-	35.409	0
IDRS Abdominal Obesity	0.482	0.191	0.142	2.531	0.012

a. Dependent Variable: FBS

Fig-2 ROC Curve for IDRS ≥60



Both over weight and obesity is seen more among females compared to males. Statistical significance (p=0.035) is seen between BMI and IDRS abdominal obesity. Abdominal obesity is dependent on BMI. (Table 2)

Interpretation: Chi square test applied between two categorical variables such as FBS (FBS categorised into <126 and > 126 as two groups) and IDRS (IDRS into two

groups <60 and > 60). Test shows IDRS scores are statistically significant (p<0.05 i.e., p=0.000) from fasting blood sugar. (Table 3) From Table 4 it is clear that there is statistical significant (p=0.012) positive correlation between IDRS abdominal obesity and fasting blood sugars.

From Table 5 prediction model also it is clear that fasting blood sugar dependent on IDRS abdominal obesity and which is statistically significant (p=0.000). From all the five tables it is clear that through Chi-square test, correlation, and through regression model IDRS abdominal obesity is a powerful predictor of diabetes. Statistical significance observed in these three tests.

Validation:

ROC curves were constructed to identify the optimum value (>60%) of IDRS for determining diabetes as diagnosed using WHO consulting group criteria. Sensitivity, specificity, positive and negative predictive values and accuracy for predicting undiagnosed diabetes were calculated for different cut off scores ROC's were obtained for IDRS and tested for newly diagnosed diabetes diagnosed using WHO criteria.

The AUC for the ROC was 0.690 (95% Confidence interval 0.601 to 0.770) with significant P value (0.0016). IDRS is valid tool for predicting diabetes.

DISCUSSION

In this study we used a simplified Indian Diabetes Risk Score for risk assessment and identifying newly diagnosed diabetic subjects in the field practise area of medical college. Further, use of such a risk score would be of great help in developing countries like India especially in urban slums[9] where there is a marked explosion of diabetes and over half of the cases remain undiagnosed. In the present study 49.92% population had high risk score (≥60) for diabetes. In a similar study[7] conducted at Chennai by Mohan et al., 43% of the population were found in high risk category to be screened with IDRS score of ≥ 60 has 72.5% sensitivity and 60.1%specificity. Another study done by Sanjay Kumar Gupta et al[10], in urban Pondicherry had 31.2% high risk subjects. This risk difference may be due to variance in life-styles of the population. Our study was done in a urban slum area, whereas Mohan et al[6], conducted the study in a metropolitan city and another study was in the urban area of Pondicherry. In Boloor diabetic study[11]by Prabha Adhikari et al 29.7% had high risk score ≥60. The prevalence of diabetes in our study is about 15.4%, and pre-diabetes is 4.5 %(total 19.9%), whereas PODIS study[9] showed 18.6% in Chennai which is a metropolitan city with affluent lifestyle.

Obesity is a potent risk factor for diabetes; in this study it is observed that obesity among females is 43.36%, among males it is 31.52%. Overweight among females is 8.96% and among males is 7.68%. Banerji et al[12], Dickinson et al[13], showed that several cross-sectional epidemiological studies suggest that obesity and abdominal obesity are strongly linked to diabetes. Sanjay kumargupta et al[10],in their study showed 39.64% are overweight, 40% are obese in Kerala which is similar to this study. Now even at low thresholds for conventional risk factors for Asian Indians.[14]

According to Eberhart, Ogden et al.[15] Approximately 55% cases of type 2 diabetes are due to obesity. Chronic obesity ultimately leads to increased insulin resistance,[16] which can develop into type 2 diabetes, because of adipose tissue (mostly that in the stomach around internal organs) is a passive source of several hormones, cytokines and chemical signals , to other tissues. Anjana et al.[17] It was found that diabetic subjects had significantly higher visceral fat (measured by CT) and central abdominal fat (measured by DEXA) compared to non-diabetic subjects, abdominal fat was significantly greater in the diabetic group. Abdominal adiposity assessed using waist circumference is considered to be more appropriate than generalised adiposity assessed by BMI by Gundurao et al.[18]

In this study screening of study population done by Indian Diabetic Risk Score developed by V Mohan et al.,(MDRF)[6]which was approved by Government of India and using in NPCDCS. The MDRF – IDRS is easy to administer and tabulate and its accuracy makes it a useful screening test for diabetes with simple four questions and one anthropometric measurement namely waist circumference.

In this study IDRS >60 has the sensitivity of 79.17% and specificity of 50.0%, in Boloor study by Prabha Adhikari et al[11], in southern part of India with sensitivity 62.2% and specificity of 73.7% and in their study they took 20 years and above as age limit. In a similar study[6]conducted at Chennai by Mohan et al., 43% of the population were found in high risk category to be screened with IDRS score of ≥ 60 has 72.5% sensitivity and 60.1%specificity.

IDRS >60 not only diagnoses diabetes also identifies[19] coronary artery disease, diabetic peripheral neuropathy, peripheral vascular disease. In the community it also helps to identify[20, 21] metabolic syndrome. IDRS can be used as tool not only for diagnosing it is a valid motivational tool[22] for life style change. This IDRS tool validated at 5 places namely Andhra Pradesh, Boloor, Madras, Pondicherry, and Vellore.

There are two steps involved in cost effective screening for diabetes at the community level. Use of Indian Diabetic Risk Score is the first step to identify persons at high risk for diabetes. Step two involves use of blood test, such as random capillary blood glucose or fasting blood sugar to further narrow validation. The validated IDRS has been successfully implemented as a practical screening tool to assess the diabetes risk and to detect undiagnosed type 2 diabetes. Moreover, it also proved suitable in prediction of metabolic syndrome and cardiovascular disease in the South Indian population. Further confirmation with GTT is required among subjects with IDRS >60 to detect early, the occurrence of diabetes. We therefore recommend that all those with FBS ≥100 mg/dl at initial screening to undergo definitive testing by OGTT as this will help to pick up everyone with any glucose intolerance, i.e., diabetes, IGT or IFG.

Besides this, lifestyle and dietary modification are to be initiated to reverse the risk factors among these people.

The limitations of our study were, use of capillary blood glucose estimation instead of venous glucose estimation, which would have been ideal. More number of female participants than male subjects in this study. The proportion of females (56%) was higher than males (44%). Men in this area are working in Municipal Corporation as drain cleaners and sweepers and they go early in the morning and come late in the evening.

ACKNOWLEDGEMENTS

I am grateful to the Indian Council of Medical Research, Delhi for the financial assistance provided for the study. I offer my special thanks to Dr. V. Mohan Sir for his suggestions and MDRF (IDF study centre for diabetes) staff for their support during my extramural training period.

Burden

Burden of combined obesity among students of a medical college in Guntur city of Andhra Pradesh

Background: Obesity is a major public health problem especially in adolescent age group. Obesity is now recognized as a chronic or non-communicable disease. Medical students are not an exception to this fast spreading epidemic, despite their medical knowledge. Few studies in fact have reported higher prevalence among medical fraternity than general population. Also, based on scientific evidence of higher proportion body fat than muscle mass among Asian Indians, the actual prevalence may be higher than what is assessed by WHO cut off for BMI. In some cases central obesity is very high in individuals whom the BMI is normal. Both BMI and WC in combination would be better predictors of obesity related diseases than sole using of BMI or WC alone. Very limited knowledge is available on combined obesity. So, we planned this study to know its burden especially among medical students. **Methodology:** It was a cross-sectional study at a medical college in Andhra Pradesh. A total of 207 medical students were selected from first and third semesters by simple random selection. Data was collected on sociodemographic data and the data of height and weight (BMI, General obesity), waist circumference (Central obesity). Finally, we estimated the burden of combined obesity (BMI+C.O). **Results:** It was observed that 35 (16.91%) medical students were having combined obesity (obesity according to BMI and waist circumference G.O + C.O). Among them 15 (20%) are male, and 20 (15.15%) are female students. **Conclusions:** The present study gives an idea about the high prevalence of combined obesity in the medical students. This should be an alert signal because medical students are the future doctors, health leaders and role models to the community. So, we need to identify specific barriers among medical students and come up with workable solutions.

Introduction

Background: Obesity is a major public health problem especially in adolescent age group. Obesity is now recognized as chronic non-communicable disease [1]. Medical students are also not an exception to come under this over weight and obesity category in spite of their medical knowledge. Stress is the major factor which contributes to obesity [2].

Medical education is highly stressful so majority of the students are having irregular unhealthy lifestyle. Due to the pressure of examinations and lack of coping skills medical students have irregular dietary habits. Medical students need to be extra conscious about overweight and obesity because its prevalence was found as high among them.

This obesity and overweight is a major risk factor for non-communicable diseases and co morbidities [3-4]. In Asian Indians evidence show that body fat is more than muscle mass. According to WHO cut off for BMI in non obese are actually obese when body fat taken into consideration [5]. In some cases central obesity is very high in individuals whom the BMI is normal which has been termed "metabolically obese" [6].

Studies shows that in The Asian Indians body fat composition is high compared to muscle mass which is the main cause for metabolic obesity. Some Indians considered non-obese by the WHO criteria of BMI cut-offs are actually obese when body fat is used to define obesity. Secondly there is a high prevalence of abdominal adiposity even in people who are otherwise considered as non-obese [7-8-9].

Central obesity is important risk factor for cardiac risk than compared to general obesity. Waist circumference is simple and easily obtainable measurement for central obesity [10-11].

In many studies BMI has taken as important parameter for obesity, but in few studies waist circumference has taken into consideration. In our study we have taken both BMI and WC combined obesity which is a potential risk factor for many diseases especially non-communicable diseases.

So this study was done with the aim to estimate the prevalence of central obesity combined with high Body Mass Index among the undergraduate medical students.

Objectives of the study: The primary objective Was to assess the burden of central obesity combined with high Body Mass Index among medical students.

Methodology

Study setting: The current study was conducted in a tertiary care teaching hospital in Andhra Pradesh

Study duration: Study was conducted for a period of twelve months in the year 2018 including study design, approval and data acquisition and analysis

Study type: Cross-sectional study

Sampling methods: We have selected 207 medical students from first and third semesters by simple random selection.

Inclusion criteria: First and third semester students of MBBS were included in the study.

Exclusion criteria: if the student was suffering from any psychiatric illness or under any antidepressant medications they were excluded from the study.

Data collection procedure: Data was collected using a structured data collection tool, comprising of self-administered close ended questionnaire on key demographic variables. The tool also had details regarding the anthropometric parameters like weight, height, waist circumference.

Initially data on self-administered questionnaire was collected in the class room, after making them seated at sufficient distance to avoid discussion and exchange of information. Later anthropometric measurements were done at the end of practical or clinical posting sessions.

Height was recorded with stature meter, while individuals stood straight with their heels, buttocks and scapula rest against a wall. Waist circumference (WC) was measured using a flexible non-elastic measuring tape. Individuals stood with their feet together, arms resting by their side.

Waist circumference was measured at the approximate midpoint between the lower margin of the last palpable rib and the top of the iliac crest according to WHO STEPS protocol [12].

The BMI was calculated using the Quetelet's equation (ratio of weight in kg and square of height in m). BMI cut off values for Indians to define overweight and obesity taken from WHO. Participants with waist circumference value higher

Than gender specific waist circumference cut off values (90 cm for males and 80 cm for females) were considered to central obesity. People with both higher BMI and higher than gender specific cut off value of waist circumference were considered as central obesity [5].

Data analysis: Data was compiled in Excel sheet and later analysed with SPSS Statistics version 21. Quantitative variables were summarized as mean and standard deviation; categorical variables were summarized as frequencies and percentages.

Association between quantitative variables was assessed by Pearson correlation coefficient. P Value < 0.05 will be considered as statistically significant.

Ethical consideration and permission: Study was commenced after Institutional ethical committee approval. Written informed consent was obtained from the participants before initiation of the study.

Results

A total of 207 students were included in the final analysis. Among 207 students, males were 75 (36.23%), females 132 (63.77%), hostellers 73 (35.3%), day scholars 134 (64.7%).

Family history nil for NCD's in 60 (29%), in 61 (29.5%) one lifestyle diseases was present, in 86 students (41.5%) more than one problem present for e.g. either hypertension, or diabetes or CAD.

Among 207 students 62 (29.9%) are not involved in any sort of exercise, 54 (26.1%) students were doing 30 minutes per day, 85(41.1%) students were involved in sports for more than 30 minutes per day.

Time spending with TV music up to one hour seen in maximum number of students 117 (56.5%), 17 students (8.2%) watching for 3 hours and more than 3 hours per day. Mobile usage of up to 1hour seen in 125 (60.4%) students, maximum of 3 hours and more seen in 33 (15.9%) students (Table 1).

Table-1: Characteristics of the study population (N=207).

Parameter	N (%)
Gender	
Male	75 (36.23 %)
Female	132 (63.77 %),
Place of residence	
Hostel	73 (35.3%),
Day scholar	134 (64.7%)
Socio economic status	
below Rs.40,000	52 (25.11%)
Rs.40,000 to Rs.1 lakh	120 (58.0%)
more than 1lakh	35 (16.9%)
Family history of NCD	
Nil	60 (29%)
One	61 (29.5%)
More than 1 NCD	86 (41.5%)
Physical activity	
Nil	62 (29.9%)
10 to 20 mints per day	6 (2.9%)
30 mints per day	54 (26.1%)
More than 30 minutes per day	85 (41.1)
Spending with TV	
Nil	11 (5.3%)
Up to 1 hour	117 (56.5%)
More than 1 hour	79 (38.2%)
Mobile phone usage	
1hour seen in	125 (60.4%)
>1 hour to <3 hours	49 (23.7)
3hours and more	33 (15.9%)

Table-2: Prevalence of Obesity as per different criteria.

Obesity	Male (N=75)	Female (N=132)	Overall (N=207)
Obesity (As per BMI)			
Yes	22 (29.33%)	27 (20.45%)	49 (23.67%)
No	53 (70.67%)	105 (79.54%)	158 (76.33%)
Obesity as per WC			
Yes	20 (26.67%)	34 (25.76%)	54 (26.09%)
No	55 (73.33%)	98 (74.24%)	153 (73.91%)
Obesity Combined			
Yes	15 (20%)	20 (15.15%)	35 (16.91%)
No	60 (80%)	112 (84.85%)	172 (83.09%)

According to waist circumference 20 males (26.67%) have central obesity (WC > 90cm), female students 34 (25.76%) have central obesity (WC > 80cm), 55 (73.33%) male students and 98 (74.24%) female students have waist circumference within normal limits (Table 2).

It was observed that 35 (16.91%) medical students were having combined obesity (obesity according to BMI and waist circumference G.O + C.O). Among them 15 (20%) are male, and 20 (15.15%) are females (Table 2).

Table-3: Correlation among different variables.

Correlations							
		Waist Circumference	Exercise	Reading	Mobile	Physical Activity	TV and Music
Waist Circumference	Pearson Correlation	1	-0.292**	0.083	-0.023	-0.320**	0.081
	Sig. (2-tailed)	-	0.000	0.236	0.741	0.000	0.245
Exercise	Pearson Correlation	-.292**	1.0	0.077	-0.008	0.723**	0.032
	Sig. (2-tailed)	<0.001	-	0.269	0.910	0.000	0.642
Reading	Pearson Correlation	0.083	0.077	1.0	-0.219**	0.263**	-0.168*
	Sig. (2-tailed)	0.236	0.269	-	0.001	0.000	0.016
Mobile	Pearson Correlation	-0.023	-0.008	-0.219**	1	0.015	0.054
	Sig. (2-tailed)	0.741	0.910	0.001	-	0.826	0.436
Physical Activity	Pearson Correlation	-0.320**	0.723**	0.263**	0.015	1	0.001
	Sig. (2-tailed)	<0.001	<0.001	<0.001	0.826	-	0.993
TV & Music	Pearson Correlation	0.081	0.032	-0.168*	0.054	0.001	1
	Sig. (2-tailed)	0.245	0.642	0.016	0.436	0.993	-
**. Correlation is significant at the 0.01 level (2-tailed).							
*. Correlation is significant at the 0.05 level (2-tailed).							

It was found significant (P<0.001) positive correlation between BMI and Waist Circumference. There is significant (P<0.001) negative correlation between Waist Circumference and exercise.

There is significant negative correlation between reading and mobile usage. TV viewing & listening music also has significant negative correlation with reading (Table 3).

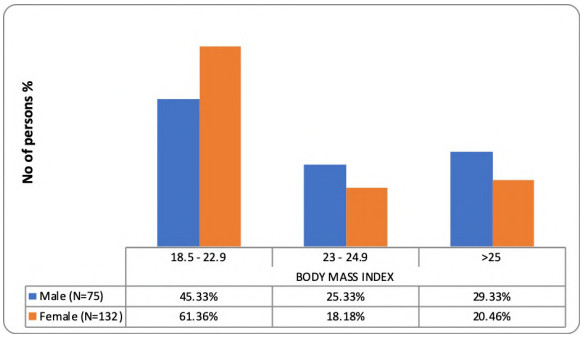

Figure 1: Prevalence of overweight and obesity according to BMI

According to BMI (WHO'S South East Asian guidelines) [13], 115 (55.56%) students comes under normal weight (BMI 18.5 to 22.9), 43 (20.77%) students comes under over weight (BMI= 23 to 24.9), 49 (23.67%) students belongs to the category of general obesity (BMI > 25) (Figure 1).

Discussion

In this study among 207 students 43 (20.77%) students are overweight and 49 (23.67%) were obese according to BMI. Central obesity according to Waist circumference observed in 54 (26.09%) medicos. Combined obesity (BMI + C.O) is seen among 35 (16.91%) medical students.

BMI and Waist circumference was positively correlated, means when BMI increasing waist circumference also increasing. Waist circumference is significantly correlated negatively with exercise or physical activity.

Similar study was conducted at Meenakshi Medical College hospital and research institute, Enathur, Kanchipuram district, Tamil Nadu, Out of 500 students, 458 (92%) participated in the study [14]. 54% among them were males and 46% were females.

The prevalence of overweight was 24.3% and the prevalence of obesity according to BMI was 8.6% according to WHO guidelines [15]. Similar study conducted at BMCRI, Bengaluru, from July-September 2014, in this study only BMI and waist circumference taken for estimating prevalence of obesity [16].

Out of the total 424 students studied, 62 (14.6%) were overweight and 48 (11.3%) were obese according to BMI. Risk factors like junk food, long hours of mobile and computer usages were taken. Out of 424 students studied, 47 males and 110 females making a sum of 157 (37%) who was considered to have central obesity according to their waist circumference [16].

Another study done at Haryana among 130 MBBS students, normal BMI was observed in 73.1%

Students, while 22.3% students were overweight, 3.1% obese [17]. A study was done at G.R medical college Gwalior among 131 second semester medical students.

In that study also BMI taken for overweight and obesity assessment and found the prevalence of overweight was 13(9.93%) and the prevalence of obesity was 2 (1.53%). The prevalence of underweight was 25 (19.08%) [18].

In this study we mainly concentrated on combined obesity which includes both BMI and waist circumference, which predicts more metabolic obesity. 20% of male students, 15.15% female students have combined obesity which is alarming.

Evidence suggests that the body composition abnormalities of Asian Indians may have an important bearing on the pathogenesis of metabolic derangements. First, their body fat is more and muscle mass less than compared with other Asian ethnic groups. Present day dietary habits, stressful routine lead to decreased physical activity is a primary drive of overweight and obesity.

Obesity leads to many medical consequences like hypertension, diabetes, coronary artery disease, stroke, and cancers. Psychological consequences are anxiety, depression, isolation, rejection, poor self-image, and poor performance and the mechanical disturbances include osteoarthritis, abdominal hernia, diaphragmatic hernia, varicose veins.

Chronic obesity ultimately leads to increased insulin resistance, because of visceral fat which is a passive source of several hormones, cytokines and chemical signals to other tissues which can develop into type 2 diabetes. Central obesity is an important predictor of metabolic disorders than BMI [19].

Obesity is not only aetiology of many diseases it also affects the quality of life and finally leads to premature death [20]. Both BMI and WC in combination would be better predictors of obesity related diseases than sole using of BMI or WC alone [21].

Medical students in this study were in prepathogenesis phase or in latent period of non-communicable diseases. The obesity problem can be reversible if we tackle them as early as possible through proper balanced diet, preventing sedentary lifestyle such as reducing TV watching time, promoting more physical activity and sports according to their interest and also coping skills for stress management.

Conclusion

The present study gives an idea about the high prevalence of overweight and obesity in the medical students. Obesity due to BMI and Waist circumference (Combined Obesity) in this study shows alarming situation in medical students. This study highlights that medicos though they are having knowledge about nutrition and physical activity could not be able to implement practically.

Students should focus on improving time management skill also they need to be encouraged to participate in physical exercise, especially sports, athletics, and other outdoor activities. Improvement in dietary habits, if made in early years of medical schooling, would produce physicians practicing and promoting healthy dietary habits. Awareness through health education was created to the medical students while measuring anthropometric measure-ments.

This should be an alert signal because medical students are the future doctors, health leaders and role models to the community. Further studies should be undertaken to identify specific barriers among medical students in practicing healthy dietary habits and come up with workable solutions. Therefore, it is of utmost importance to have early intervention programmes to prevent non-communicable diseases among these future doctors.

What this study adds to existing knowledge

The study had highlighted the prevalence of different types of overweight and obesity among medical students. The key addition of the study was it’s documentation of overall and central obesity and their overlap among the study population. The study highlights the importance assessing waist circumference, along with BMI, to avoid underestimation of the true burden of overweight and obesity.

Author contribution

Dr. SS had conceptualized the study, prepared the study protocol, and conducted the data collection, analysis and manuscript writing. She has verified all the drafts and approved the final draft. Dr. SD had provided key inputs on methodology during protocol preparation, supported data compilation and analysis. She has also edited all the drafts and

Approved the final draft of the manuscript.

Acknowledgements

We express our sincere and heart full gratitude to the opportunity and support provided by the Dean of Katuri Medical College and Hospital Guntur (A.P). We are extremely thankful for the support provided by our faculties of Department of Community Medicine and Department of Physiology (GMC). Last but the most, we would like to thank all the MBBS students of first, and third semester of Katuri Medical College and Hospital for their cooperation, without whom this study would not be possible.

Limitations

First, the sample used in this study was a convenient sample and thus findings need to be interpreted with caution. Further qualitative studies are needed for better understanding to plan for interventions.

ABSTRACT

Background: Travelers play a significant role in the spread of infectious diseases across international borders, through their travel patterns and behaviors. Travel may be the only risk factor for infectious diseases that are well controlled in the travelers' country of residence, particularly vaccine-preventable diseases. **Objectives:** The aim of this study is to assess the knowledge and practice of travel vaccination and malaria prophylaxis among resident doctors of BJ Medical College and Civil Hospital, Ahmedabad. **Materials and Methods:** This was a cross-sectional study conducted at Civil Hospital and BJ Medical College, Ahmedabad. The study was conducted from July 2017 to October 2017. A pilot study was conducted among 20 resident doctors, and the prevalence of knowledge of travel vaccination was found to be 65%. Using the formula $4pq/L^2$, data were collected from 100 resident doctors. Data were collected using a semi-structured questionnaire, and data analysis was performed using Microsoft Excel 2013 and EpiInfo 7. For statistical analysis, Chi-square test was applied. Ethical consent was taken from all respondents. **Results:** 86% of the resident doctors were having knowledge about travel vaccination, and 79% were knowing about the requirement of malaria prophylaxis given to travelers. The travel vaccine knowledge was 100% among the persons above 30 years of age, and it was 86% in the younger age group (20–25 years). Country-wise knowledge about travel vaccination was more for developing countries than developed countries. Only 8.3% gave the history of taking immunization for international travel. Reasons for not taking immunization were not required for country of travel followed by non-awareness. **Conclusion:** The knowledge of travel vaccine and malaria prophylaxis was more among the 30+ age group followed by 20–25 age groups, and the knowledge of both was more among males. The practice of travel vaccination was found to be poor.

KEY WORDS: Travel Vaccination; Malaria Prophylaxis; Resident Doctors

INTRODUCTION

Travelers often play an important role in the spread of infectious diseases across borders, through their travel plans, behaviors, and patterns. Traveling might be the only risk factor for the transmission of infectious diseases that are well controlled in a certain country, especially vaccine-preventable diseases. The role of vaccination among travelers is a significant component for the prevention of travel associated infectious diseases.[1,2]

Health risks associated with travel need to be balanced against the positive opportunities offered by inter-regional and cross-border travel.[3] The main goal of travel health and associated fields is to protect travelers from disease, accidents, and death. International travel has seen a dramatic rise during

recent times, and there has been an increase in diseases and associated public health problems. Each year, around 80 million travelers from developed countries visit developing countries where the epidemiological and sanitary conditions are different from their country of residence.[4] Thus, travelers increase the risk of exposure to travel associated health problems which include infectious diseases that may be imported back to their home country.[5]

Immunizations taken before traveling contribute to the risk reduction of specific diseases for the traveler as well as the reduction in risk of international spread of diseases. Agent, host, and environmental factors determine the risk of acquiring a disease when traveling. Most significant factors are the place that has to be visited, travel duration, and reason for travel. Among host factors, the traveler's health and his/her behavior overseas have to be considered. As a result, an agent–host–environment-based assessment of the travel plan should be done when considering which immunizations are to be taken by the traveler.[6]

India has become a popular destination for tourists in South Asia. Recent economic opportunities have resulted in a remarkable increase of business-related travel. People traveling to India can be broadly divided into the business traveler, the young economical backpacker, the medical volunteer, the holiday tourist, and the immigrant or non-resident Indian visiting family and friends. Medical graduates in India are showing interest in international travel to different countries for higher specialist courses, career growth, and better opportunities. People traveling to India are at an intermediate risk for malaria, and recent reports in the rise of chloroquine-resistant *Plasmodium falciparum* malaria in various parts of India are causing a rise in concern. Furthermore, different international travel advisory bodies vary on their opinion for malaria prophylactic regimens to be followed when traveling to India.[7-9]

Improvement in the knowledge and health education of disease transmission among travelers, following recommendations on sanitation, food, and water hygiene, avoiding arthropod bites with physical barrier methods and insect repellents, chemical prophylaxis against malaria, and taking required vaccinations are all known to reduce the risk of travel-associated diseases.[10] Since a considerable amount of travelers are at risk for having a travel-related illness or injury during their outings, there is a need for travelers to seek suitable pre-travel health education and immunizations to reduce the risk of any ailment while away from their country of residence.[11]

Objectives

The objective of this study is to assess the knowledge and practice of travel vaccination and malaria prophylaxis among resident doctors of BJ Medical College and Civil Hospital, Ahmedabad.

MATERIALS AND METHODS

A cross-sectional study was conducted at BJ Medical College and Civil Hospital, Ahmedabad. The study was conducted from July 2017 to October 2017.

A pilot study was conducted among 20 resident doctors, and the prevalence of knowledge of travel vaccination was found to be 65%. Using the formula $4pq/L^2$, data were collected from 100 resident doctors of Civil Hospital and BJ Medical College, Ahmedabad.

Data were collected using a semi-structured questionnaire, and data analysis was performed with Microsoft Excel 2013 and Epi Info 7. For statistical analysis, Chi-square test was applied. Ethical consent was taken from all respondents.

RESULTS

Figure 1 shows that 86% of the respondents had knowledge about travel vaccination while 79% of the respondents had knowledge about malaria prophylaxis.

As per the practice of travel vaccination, of the 24% who traveled, only 2 (8.3%) gave the history of taking immunization. Reasons for not taking immunization were not required for country of travel followed by non-awareness.

Table 1 shows that knowledge about travel vaccination was more in the 30+ age group (100.0%) followed by

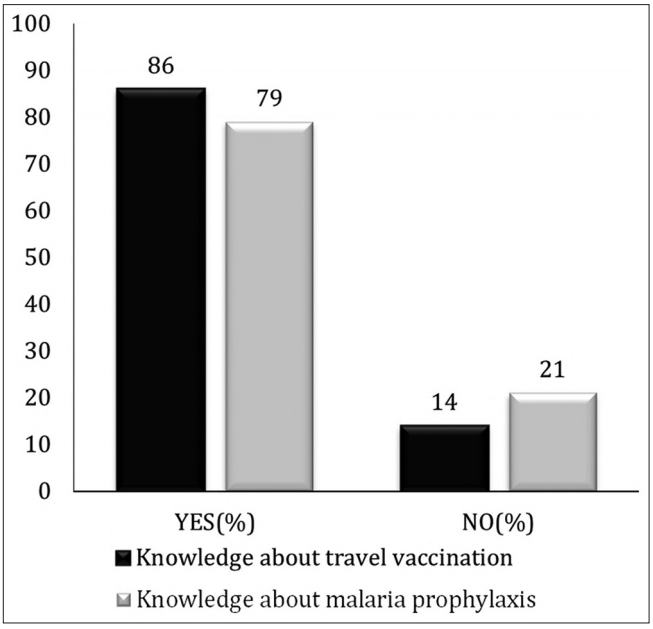

Figure 1: Overall knowledge about travel vaccination and malaria prophylaxis

Table 1: Relation of knowledge about travel vaccination with sociodemographic variables

Parameters	Respondents			
	Total	Having knowledge *n* (%)	Not having knowledge *n* (%)	*P* value

Qualification				
1st-year resident	49	40 (81.6)	9 (18.4)	*P*=0.47
2nd-year resident	25	17 (68.0)	8 (32.0)	
3rd-year resident	26	22 (84.6)	4 (15.4)	

the 20–25 years age group (86.3%) while those in the 26–30 years age group (82.9%) had the least knowledge. Knowledge was more in males (90.2%) compared to females (81.6%). Married respondents showed more knowledge (89.3%) compared to single respondents (84.7%). Knowledge about travel vaccination was highest among 3rd-year resident doctors (88.5%), followed by 1st-year residents (85.7%) and then 2nd-year Residents (84.0%).

Table 3: Country-wise knowledge about travel vaccination was more for developing countries than developed countries

Region	Percentage
USA	6
Europe	5
Australia	16
Africa	49
Southeast Asia	18
Arabian countries	13

However, no statistical significance was found between the sociodemographic variables with knowledge about travel vaccination ($P > 0.05$).

Table 2 shows that knowledge about malaria prophylaxis was more in the 30+ age group (87.5%) followed by the 20–25 years age group (86.3%) while those in the 26–30 years age group (68.3%) had the least knowledge. Knowledge was more in males (84.3%) compared to females (73.5%). Single respondents showed more knowledge (79.2%) compared to married respondents (78.6%). Knowledge about travel vaccination was highest among 3rd-year resident doctors (84.6%), followed by 1st-year residents (81.6%) and then 2nd-year residents (68.0%). However, no statistical significance was found between the sociodemographic variables with knowledge about malaria prophylaxis ($P > 0.05$).

Table 3 shows that country-wise knowledge about travel vaccination was more for developing countries compared to developed countries with that for Africa being the highest (49%) and that of Europe being the least (5%).

Figure 2 shows that 71% of the respondents were aware about the malaria chemoprophylaxis drug regimen compared to 29% which were unaware.

DISCUSSION

In our study, 86% of the respondents had knowledge about travel vaccination while 79% of the respondents had knowledge about malaria prophylaxis. In a similar study conducted in Nigeria, the knowledge about travel vaccination was found to be 96.3%.[1]

Most respondents were between 20 and 25 years of age, while in other similar studies conducted in Nigeria, Qatar, and America, majority of the respondents were of a higher age.[1,5,12] This study has an almost equal proportion of male and female respondents which is similar to an American study.[12] On the other hand, the number of male respondents were predominant in studies conducted in Nigeria and Australia, while the number of females were more in a Qatar

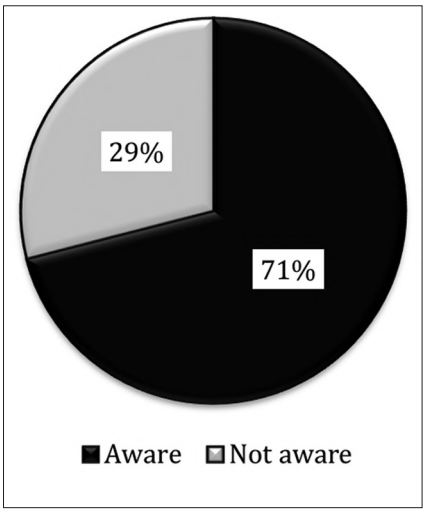

Figure 2: Awareness about malaria chemoprophylaxis drug regimen

study.[1,5,13] Most of the respondents were single which was contrary to a study conducted in Nigeria where most of the respondents were married.[1]

The practice of travel vaccination in this study was found to be very low which was similar to the findings of an Australian and Bangkok study but different from Greek and Nigerian studies where the practice of travel vaccination was found to be high.[1,2,13,14] Reasons of low practice in this study were not required for country of vaccination followed by non-awareness, while in other studies, the reasons were paucity of information on travel vaccination, distressing protocols and requirement for the vaccination, cost of vaccination as well as poor monitoring system for ensuring travel vaccination at the entry and exit points of the countries, unaware of being at risk, low knowledge of vaccination being important for traveling, cost of the vaccination, and side effects.[1,10,14]

The knowledge about travel vaccination and malaria prophylaxis was found to be good in this study which was similar to the results of other studies.[1,5,10,12-15]

Strength

The relation of sociodemographic variables with knowledge about travel vaccination and malaria prophylaxis is compared which has not been done in similar studies.

Limitation

The relation between knowledge about travel vaccination and malaria prophylaxis with sociodemographic variables was found to be insignificant, so the study should be carried out by taking a larger sample.

Recommendations

Doctors need to be updated on the latest norms of travel vaccination and malaria prophylaxis with special emphasis to be given on the importance of the practice of vaccination during international travel. This may be added to the academic curriculum because many doctors are interested in international career prospects.

CONCLUSION

It seems that the knowledge of travel vaccine and malaria prophylaxis was more among the 30+ age group followed by 20–25 age groups, and the knowledge of both was more among males. The married doctors showed more knowledge about travel vaccines, but the knowledge of malaria prophylaxis was more among single doctors. 3rd-year residents had more knowledge about both. The above groups may be more aware as they may be contemplating foreign travel in the near future. The practice of travel vaccination was found to be poor. Overall knowledge of travel vaccination and malaria prophylaxis was good.

Rapid Assessment of Nutritional Status of Children in Rural Area of Maharashtra

Agrawal KH[1], Bhatta B[1], Agrawal NH[2]

ABSTRACT

Introduction: Assessment of nutritional status by anthropometry is the simplest and most useful tool for assessing the nutritional status of children. Given the importance of nutrition in early life, this study was conducted among children between 12-36 months. Aim: To study the nutritional status of children between 12-36 months and factors associated with it.

Material and Methods: Settings: Catchment area of Kheda Primary Health Centre, Dhule. Design: Cross-sectional study based on 30 cluster sampling technique. Sample size: Worked out to be 210. Participants: 210 children between 12-36 months in 30 clusters. Study variables: Mid Upper arm Circumference measurement of children, gender, birth order, social categories, literacy status of parents, occupation of father, nuclear or joint family. Statistical analysis used: Chi square test of significance, descriptive analysis (mean -mode –median).

Results: Based on the Mid Upper Arm Circumference, the overall prevalence of malnutrition among children was 40%. The prevalence of severe malnutrition was 13%, with higher prevalence in females as compared to males. Statistically significant association was seen between malnutrition and gender of children, birth order, social categories (especially children belonging to Scheduled Tribes), literacy status of parents and type of family.

Conclusions: There is a need for geo-social mapping and "inclusion sensitive" microplanning, especially to ensure equitable access (in terms of support and information) to excluded social categories to reduce the magnitude of malnutrition.

Keywords: Malnutrition, mid upper arm circumference, social exclusion, Scheduled Tribes.

INTRODUCTION

A child is not a miniature form of adult. Growth is an indispensable feature of life of a child that distinguishes him from an adult. Environment experiences of the child during postnatal life determine the pace and pattern of his growth and development.[1]

Malnutrition is widely recognized as a major public health problem in the developing countries of the world including India. Based on the United Nations Children's fund (UNICEF) report, malnutrition in early childhood has serious, long term consequences because it delays motor, sensory, cognitive, social and emotional development.[2] Malnourished children are at a greater risk to grow into malnourished adults.[2] The prevalence of Undernutrition cannot be easily estimated from the prevalence of commonly recognized clinical syndromes of malnutrition such as marasmus and kwashiorkor because these constitute only proverbial tip of iceberg. Cases with mild to moderate Undernutrition are likely to remain unrecognized because clinical criteria for their diagnosis are inaccurate and difficult to interpret precisely.[3]

Child growth is commonly used to assess adequate nutrition, health and development of individual children and in comparison with other health assessment tools its measurement is a relatively inexpensive and easy to perform procedure.[4] Therefore, anthropometric examination is a mandatory tool in any research on health and nutritional condition in childhood.[5] Moreover, in community based studies, mid upper arm circumference (henceforth called as MUAC) appears to be a superior predictor of childhood mortality than many other anthropometric indicators.[4] MUAC yields a relatively reliable estimation of the body's muscle mass, the reduction of which is one of the most striking mechanisms by which the body adjusts to inadequate energy intakes.[6] Arm circumference cannot be used before the age of one year; between ages one and five years, it hardly varies.[6] Large studies in Latin America and South Asia have clearly established the reliability of arm circumference screening as an effective method of identifying malnourished children.[7]

During preschool age period, children have special nutrition needs because of their extensive growth and development.[4] Moreover, the direct effect of malnutrition is believed to operate largely in the first two or three years of life.[8]

With this background we decided to conduct a survey to rapidly assess the nutritional status of children between 12-36 months and factors associated with it by measuring the MUAC in the catchment area of Kheda Primary Health Centre of district Dhule, Maharashtra. The data collected would also benefit the district authorities to prepare a district action plan to address the problem of malnutrition in children in Dhule district.

MATERIAL AND METHODS

The survey was conducted in the catchment area of Kheda Primary Health Center, Dhule district, Maharashtra, India carried out from 23rd October to 1st November 2011. This Primary Health Center (henceforth called as PHC) caters to population of 38465 distributed among 30 hamlets (within 12 villages).

Approval of institutional ethical committee (IEC) and district health authorities were taken before conducting the survey. The survey design used in the current study is the World Health Organization 30X7 cluster survey method. This is a cluster

[1]Associate Professor, Department of Community Medicine, Gandaki Medical College, Pokhara, Nepal, [2]Associate Director-PSE, JHPIEGO, New Delhi, India

How to cite this article: Agrawal KH, Bhatta B, Agrawal NH. Rapid assessment of nutritional status of children in rural area of Maharashtra. International Journal of Contemporary Medical Research 2016;3(7):2082-2086.

sampling technique. This technique allows a small number of the target population to be sampled while providing statistically valid data that can be extrapolated to the whole target population. The 30 hamlets (within the 12 villages) under the catchment area of Primary Health Center formed the sampling frame for the cluster sampling technique. The target age group comprised of children aged 12-36 months. The random number and sampling interval were worked out to be 1117 and 1282. The determination of sample size was done as per the WHO 30X7 cluster survey – "Reference Manual" in the same way it is done to evaluate the immunization coverage.[9] For sample size determinations to assess the nutrition status, the following were determined, estimated or assumed beforehand:

- Anticipated level of prevalence of malnutrition in children – 60%;
- Desired precision of the estimate - ± 10%;
- The level of statistical confidence of the estimate (confidence level) - 0.05;
- Magnitude of differences of coverage among and within the clusters (design effect) - 2.

The total sample size was estimated (the total number of children to be surveyed) using the equation below.

$$n_{min} = DE \times \frac{z^2_{1-\alpha/2} \times p \times (1-p)}{d^2}$$

- Where p is expected prevalence, d is the desired width of CI, DE is design effect and Z is the multiplier from the normal distribution for the desired confidence level (α)
- Assuming a DE of 2 and d of 0.1, the minimum sample size worked out to 184.

Since we were going to use 30 clusters, the sample size per cluster worked out to 184/30 = 6.13. Rounded off, number of children to be surveyed in each of the 30 clusters was 7. Thus 210 children was the total sample size for 30 cluster survey. Keeping in view that, cluster is a collection of households with identifiable geographical boundaries; hamlet-wise population was obtained from PHC (cross checked with population data provided by Gram Panchayat) and taking 1117 as random number and 1282 as sampling interval 30 clusters were identified by using the standard technique.[9]

The field implementation for the survey was conducted as per a detailed plan devised beforehand. Establishing of households of the selected clusters was not going to be possible. Therefore the investigators decided that in every cluster, the geographical center of the cluster would be visited. From there, the investigators would move in a randomly chosen direction. The first house would be the house corresponding to a random number chosen beforehand. Both, the direction in which the investigator would move and the random number for choosing the first house, were generated using the computer for each cluster. After visiting the first household the second household to be visited was the one that was nearest to the first.

Interviews and Collection of Data: The investigators conducted interviews as per a pre-structured, pilot-tested interview format in households with children between 12-36 months. The MUAC of the children was measured and their socio-demographic profile was taken. Utmost care was taken at the time of measuring MUAC. The study teams were trained in taking MUAC to minimise the inter observer variations. The non-dominant upper arm was chosen for the measurement and the circumference of location in between the tip of the shoulder and the tip of the elbow (olecranon process and the acromian process)while the arm is hanging down the side of body and relaxed was considered as MUAC. Flexible measuring tape was used for measurement of MUAC. Arnold's classification[10] was used to classify malnutrition based on the MUAC. An arm circumference exceeding 13.5 cm was considered as a sign of a satisfactory nutritional status, between 12.5 cm and 13.5 cm was considered to indicate as mild-moderate malnutrition and below 12.5 cm, severe malnutrition.[6] The socio-demographic profile comprised of gender of the child, birth order, religion, social categories, father's occupation and education, mother's education, type of family (joint or nuclear).

Inclusion criteria: Children between 12-36 months with availability of responsible person for key information. All records entered were checked, cross-checked and randomly double checked for correctness.

Informed consent from all parents of the children was obtained. The parents of the children had the option to opt out of the study if they wished to. However, no parent refused to participate and thus there was 100% response.

STATISTICAL ANALYSIS

Chi square test of significance, descriptive analysis (mean-mode- median) were used to infer results with the help of SPSS 16.0 version.

RESULTS

A total of 210 children were included in the study, of which 107 (51%) were male and 103 (49%) were female children. Overall prevalence of malnutrition (MUAC ≤ 13.4 cm) in children was found to be 40% (36.4% males and 43.7% females).The prevalence of severe malnutrition (MUAC ≤ 12.4 cm) was found to be nearly 13% (7.5% males and 19.41% females). There were 10 (4.8%) children having MUAC 11.5 cm or less.

For overall prevalence of malnutrition, the sex differential was not statistically significant (P>0.05). Sex differential was though statistically significant (P<0.05) for prevalence of severe malnutrition.

Table-2 depicts MUAC distribution according to socio-demographic factors. It was observed that only 33.7% children with birth order 2 or less than 2 were malnourished. On the contrary, 60.5% children were malnourished when their birth order was 3 or higher. The difference was statistically significant. Additionally, 66% children with birth order 2 or less were found to be having satisfactory nutrition status (MUAC>13.5 CM), while, only 31.6% children with birth order 3 or higher were observed to be having satisfactory nutrition status, the difference being statistically significant (P<0.05).

Substantial differences in the status of nutrition were observed

MUAC	Number (%)
< 12.5 cm	28 (13.3)
12.5-13.4 cm	56 (26.7)
≥ 13.5 cm	126 (60)
Total	210 (100)

* Social Categories of India - Scheduled Tribes (ST) and Scheduled Castes (SCs) are the socially depressed classes of India. OBCs are other backward classes. "Higher" social classes are classified as Others.

Table-2: Distribution of Mid Upper Arm Circumference (MUAC) by different variables.

among children belonging to Scheduled Tribe (ST) category and children belonging to higher category (others). There were higher chances of higher category children (90.4%) being well nourished as compared to children belonging to ST category (37.9) and this probability was observed to be statistically significant (P=0.029). Similarly, the prevalence of malnutrition (mild-moderate and severe) was also found to be higher (62%) among children belonging to ST social category as compared to children belonging to higher social category (9.5%) and this difference was found to be very significant statistically (P=0.0064).

Better education status of the mother had a positive impact on the nutrition status of children. The overall prevalence of satisfactory nutrition status (MUAC >13.5 cm) was high among the children (74.4%) having literate mothers (high school and above education) as compared to children (39.7%) with illiterate mothers. This difference was statistically significant (P=0.02). Children with illiterate mothers also had a higher probability of being malnourished (60.3%) as compared to children with literate mothers (high school and above education). This difference was extremely statistically significant (P=0.0032). It was revealed further that the prevalence of malnutrition among the children with literate fathers was comparatively lower (21.5%) than the illiterate fathers (75.6%) and the difference was also statistically very significant (P=.0020).

Lastly, it was observed that children belonging to nuclear family had higher prevalence of severe malnutrition (27.3%) as compared to children belonging to joint family (8.4%). The difference was considered to be statistically very significant (P=0.0068).

Table-3 gives the insight of statistical averages and measures of dispersion (standard deviation) of MUAC of sampled children by some social categories. The most striking feature is the statistical averages of MUAC of children belonging to Scheduled Tribes. The mean MUAC of these children is 13.33 cm (standard deviation-0.99), while the median is 13.25 cm. The mean and median are all below cut off point for malnutrition i.e. 13.5 cm.

Variables	Mean (cm)	Median (cm)	Standard Deviation
ST	13.33	13.25	0.99
SC	13.05	13.5	1.27
OBC	13.81	14	0.91
Others	13.9	14	0.7

Table-3: Mean Median and Standard Deviation of MUAC by different variables.

DISCUSSION

Nutrition is one of the important social determinants of health. In the last few years, state of Maharashtra has made significant progress in reducing infant mortality rate and maternal mortality rate.[8] The state also has significant economic growth. However, despite this context, the state has not been able to make much significant progress in improving the nutritional status of the population[8] which can be reflected by its Hunger index rank (The Indian state hunger index is computed by averaging the three underlying components of hunger index-the proportion of underweight children, the under-five mortality rate, and the prevalence of calorie Undernutrition in the population).[8] The Indian state Hunger index rank of Maharashtra is poor as compared to other Indian states which are not as economically well off. The global comparison of the hunger index rank also reveals that Maharashtra is behind some low income African and Asian countries such as Rwanda, Burkina Faso and Cambodia.[8] The question that needs to be answered here is, whether economic prosperity translates into adequate nutrition of the community?

Myatt et all in their review study in 2006 concluded that mid upper arm circumference is the best case detection method for severe malnutrition and that it is also simple, inexpensive and acceptable.[11] Velzeboer implicated in their study that, MUAC can be taken by minimally trained health workers with fewer and smaller errors as compared to other anthropometric measurements (weight for age and weight for height).[12] Given the situation that malnutrition is a major public health problem in India, can we train our grass root level workers (especially the Anganwadi workers) in mid upper arm circumference measurement to screen the children nutritionally? The question needs to be answered.

In the present study, the overall prevalence of malnutrition is 40%, while, the prevalence of severe malnutrition is 13%. The review of literature (ROL) indicates no such mid upper arm circumference based malnutrition study in Maharashtra. Thus, we are unable to compare our findings with similar studies in Maharashtra. In rest of India context, prevalence of overall malnutrition in the present study is higher than the earlier studies conducted at Orissa (31%)[13] and Punjab (38.5%)[14] States. This might be due to higher proportion of children belonging to Scheduled Tribes in our study. Based on National Nutrition Monitoring Bureau (NNMB) survey finding, in Maharashtra less than one third of the children in the age group of 1-3 years consume the recommended dietary allowances of proteins and calories. Moreover, the data on food consumption reveal that consumption of cereals and millets is only 69% (averagely) of what children need. They consume only half of the required quantity of pulses and legumes.[8]

More number of females were malnourished than males in our study, with statistical significance in pertinence to severe malnutrition. This could be due to gender bias particularly with respect to intra familial food distribution prevalent in Indian society. Similar finding was reported by Ahmad et al (2011).[15] Children with birth order one and two had better nutritional status than with higher birth order. This could be explained by the fact that in our study, large family norm was practiced by families belonging to Scheduled Tribes. Similar finding was reported by Harishankar et al (2004).[16] They opined in their study that, the proportion of malnourished children was significantly lower in birth order one as compared to birth order three and higher.[16] It was observed that, better educational status of parents had a positive impact on the nutritional status of children. Educated parents are more aware about their child's health and have a better chance of utilizing the health services as compared to the illiterate ones. This finding is suggestive of a strong association between parental literacy and nutritional status of children.

One of the main highlight of the study is the significant association of social category of the child and his/her nutritional status. The proportion of malnourished children was extremely high in ST children. Additionally, the mean, median and mode MUAC of children belonging to ST were all below cut off point for malnutrition i.e. 13.5 cm. We would like to suggest that study should be conducted on the dietary patterns (including the food habits and food fads) of the families belonging to ST social category to understand their consumption unit (CU). Given that Maharashtra and Dhule district have a large ST population, understanding the dietary patterns of these families will definitely have an impact on understanding the problem of malnutrition clearly, which eventually will help in addressing its problem.

CONCLUSION

The present study amply reveals that, as far as the child nutrition is concerned, the Scheduled Tribes seems to be the socially excluded groups among all the social categories. We think that there is a need for area specific, geo-social mapping and "inclusion sensitive" microplanning, especially to ensure equitable access (in terms of support and information) to excluded social categories in order to accomplish the goal of reducing malnutrition. Support may be in terms of knowledge and significance of best practices such as exclusive breastfeeding for first six months, starting nutritive semisolid at 6 months, use of locally available and inexpensive foods, child feeding practices, identification of risk of malnutrition etc. The role of Anganwadi workers (grass root health workers in India) seems to be critical in this.

Abstract

Background: Drug abuse affects the health and lives of millions of individuals across the world. Discrimination faced by substance users and stigmatization becomes a barrier for them thus these patients do not receive the required care and treatment they deserve. The negative perception of healthcare professionals leads to poor therapeutic alliance between them and the patients of substance use. Current study aims to determine and assess the attitudes of the health professionals towards patients with substance use problems and to identify factors causing diverse attitudes of health professionals towards these patients.

Method:A questionnaire based cross sectional study was undertaken at Ananta hospital Rajsamand (a tertiary health care centre) which included 134 health professionals both doctor and nursing staff for a duration of one year who provided their consent for this project. The socio- demographic details of every participant was collected and all of them were given the DDPPQ tool which assessed their attitudes and perception towards drug and drug use problems.

Results: Younger age group of health professionals showed better outlook towards patients of drug abuse. A linear regression of gender, professional roles (i.e. doctors and nurses), past history of substance abuse and known history of substance abuser in the family with the principal component does not yield any significant results. Majority of the participants had either neutral opinion or positive opinion towards the problem of drug use and the drug users.

Conclusions: Healthcare professionals with age on the lower side had more positive regards and significantly positive attitudes towards the problems of substance use and therefore the

therapeutic compliance was better. Healthcare delivery needs unbiased and non-judgmental attitude of healthcare professionals towards patients of substance abuse, so in an attempt to provide holistic approach and care that overlooks socio-demographic and clinical profiles, professionals should have adequate and appropriate training and exposure accordingly.

Keywords: Professionals, nursing, staff, substance, drug, perception, attitudes, stigmatization.

Introduction

Drug abuse is a global phenomenon which affects almost every country with a variable extent. Abuse of illicit drug affects the health and lives of many individuals across the globe. The criminalization of this addictive behavior damages the reputation of the engaged person and it also deters other people, leading to stigmatization of the problem in the society. Stigmatization also discourages illicit drug users from getting health care due to fear of poor treatment by health care providers or fear of trouble with the authorities[1,2]. While stigma and discrimination may serve as deterrents to illicit drug use, these attitudes also contribute to discrimination and stigmatization experienced by illicit drug users which may be bad for drug user's health[3]. Negative attitudes of health professionals towards patients with an alcohol or other drug addiction are known to lead to poor communication between professional and patient, diminished therapeutic alliance, and mis-attribution of physical illness symptoms to substance use problems, also referred to as diagnostic overshadowing[4,5].

In this scenario, medical professionals are key persons in the provision of care for persons who exhibit problems related to use of the substances of abuse. Personal factors[6] and deficient medical education about addiction in health professionals[7] influence the under-diagnosis of substance abuse disorders. Studies have found that physicians were significantly less satisfied when caring for patients with drug problems compared to other illnesses[8]. A study on nurses found that nurses struggled with the care for patients who use illicit drugs and they had less motivation, satisfaction, role support and education[9]. Another study found that staff who had received training held fewer negative attitudes towards illicit substance users regardless of their length of clinical work experience or type of work setting[10]. Another study found that health professionals' regard was lowest for patients with drug and alcohol problems, lowest regard was found among physicians who did not work in specialized addiction services[11]. This study found that specially trained personnel's in this field such as psychologists, social workers, and professionals in the addiction services showed the highest regard while physicians who did not work in specialized addiction services had lowest regard. People with drug related disorders deserve the same level of care as patient with any other health condition. Health service need to be able to identify drug use and drug use disorder at an early stage and provide prevention, treatment and harm reduction intervention. We could not find any study in our region addressing health professional attitudes towards persons with problems related to substance use.

Aims and Objectives

Current study aims to assess and determine the attitudes of the health professionals

towards patients with substance use problems and to identify factors causing diverse attitudes of health professionals towards these patients.

Methods

Study area

The study was conducted at Ananta Hospital Rajsamand (attached to Ananta Institute of Medical Science and Research Centre, Rajsamand, Rajasthan) a tertiary care hospital.

Study Design

Questionnaire based cross sectional study

Study Participants

Health Professionals (Including doctors and nursing staff)

Study duration

One Year, September 2019 to August 2020.

Sample size

A total population of health care professional of 200 working in Ananta Institute of Medical Science and Research Centre, Rajsamand, Rajasthan, a tertiary care hospital. Minimum of 134 participants were expected to participate according to the following calculation.

$N^* = N*X / (X + N - 1)$,

where,

$$X = Z^2_{1-\alpha}\, p(1-P)/d^2$$

where alpha (α) = 0.05, estimated proportion (p) = 0.50, estimated error (d) = 0.05 and N is the population size

The Finite Population Correction is used to adjust a variance estimate when sampling without replacement.[15]

A stratified random sampling technique has been used for collection of data. A validated 22-item DDPPQ questionnaire tool has been used in the study.

Statistical analysis

Questionnaire data was analyzed using SPSS version 24. Socio demographic data were summarized using frequencies and percentages. Means and standard deviation were used for continuous variables. Mann Whitney U test was used to compare the difference among professional groups i.e. doctors and nurses. The relationship between DDPPQ scores and other relevant variables was analyzed by using Pearson Product-Moment Correlation Co-efficient. The regression analysis has been done to find out relationship between independent and dependent variables. Statistical significance was taken at the 5% level.

Data Collection Procedure

The 22-item validated version of Drug and Drug problems perception questionnaire (DDPPQ) instrument was used for the study[12]. The validated DDPPQ, comprises of 22 items and is a shorter questionnaire, having retained only the most reliable items from the original instrument. The items of the validated questionnaire are numbered consecutively from one to twenty-two. The validated DDPPQ is a self-complete 'paper and pencil' questionnaire. Respondents are asked to rate their level of agreement on a series of 22 statements about working with people who use licit or illicit drugs in a nontherapeutic way. There are seven possible responses to each item on a scale of Strongly agree' to 'Strongly disagree'. Low scores denote positive attitudes, whereas high scores are associated with negative views. Several of the items are worded negatively. These are Items 15, 16, 17 and 18. For the purpose of this study, the DDPPQ were expressed on a 5-point Likert scale ranging from 1 = strongly agree, 2 = agree, 3 =neither agree nor disagree, 4 = disagree to 5= strongly disagree

.A 5 - point Likert-type scale instead of 7-point was used to increase response rate and response quality along with reducing respondents' frustration level[13]. Factor structure of the validated DDPPQ has yielded its six factors which are role adequacy, motivation, role legitimacy, task specific self-esteem, role support and work satisfaction

Study Variables

The independent variables in the study are the socio-demographic characteristics of the study participants such as gender, age, profession, work motivation and role support of health professional. The dependent variables, attitude and perception are measured by six factors/ subscale measure (using 5- point Likert scale) in the DDPPQ. Questionnaire data was analyzed using SPSS version 24. Socio-demographic data were summarized using frequencies and percentages. Data was analyzed by using unrelated T-test, Mann Whitney U test and Pearson product moment correlation coefficient.

For the questionnaire survey, 22 items of validated version of DDPPQ questionnaire was distributed individually to the 152 professional group members in a sealed envelope and returned back in same sealed condition in order to maintain privacy of participants. One hundred and thirty-four participants returned the completely filled up questionnaire. All professional group members i.e. both doctors and nursing staff members responses to the given DDPPQ questionnaire were calculated to give a total attitude score. The minimum score for the DDPPQ is 22 and the maximum score is 110. The higher the score obtained indicates an increasingly more negative attitude.

Results

Table 1: gives description of number of participants according to the gender as well their professional roles.

Group	Number (Total=134)	Percentage
Doctors	85	63.4 %
Males	53	39.5 %
Females	32	23.8 %
Nursing staff	49	36.5 %
Males	30	22.3 %
Females	19	14.1 %

Table 1. Profile of the Sample

Table 2: shows profile of the sample according to professional group and gender.

	Number of responses	Score Range	Mean Score (SD)	Z score	P* Value
Doctors	85	24-76	49.63 (8.95)	-0.30	0.75
Nursing Staff	49	33-68	49.46 (9.52)		

Table 2. The DDPPQ Score Range for Professional Groups

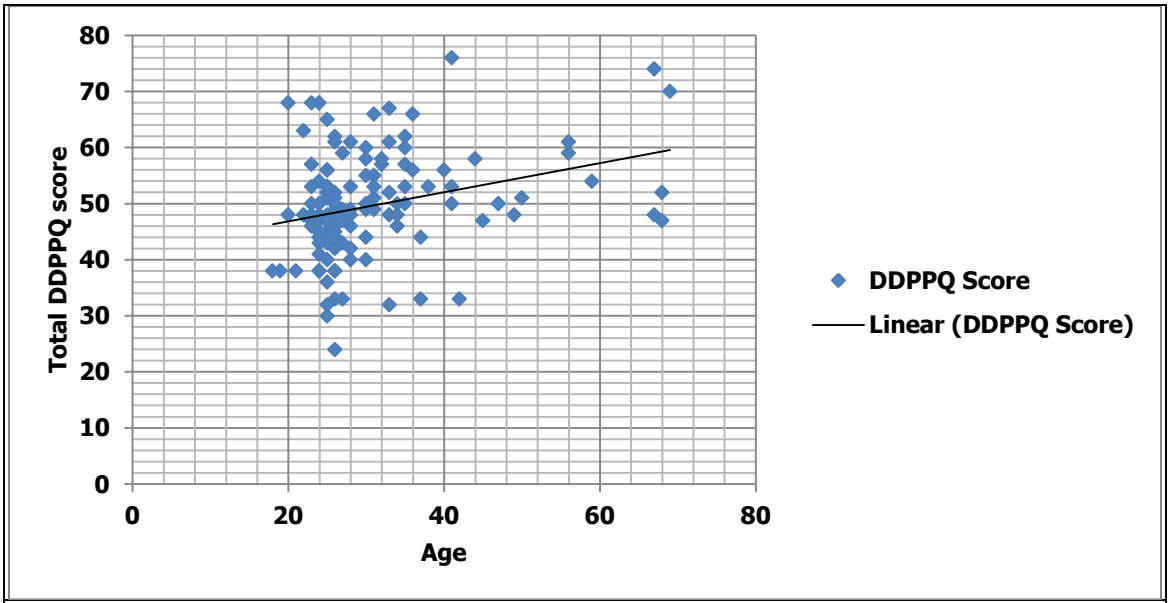
Mann Whitney U test. * The result is significant at $p<0.05$

Table 2 shows the DDPPQ score range for the participants. A Mann-Whitney U test was conducted to compare DDPPQ scores between doctor and nursing staff. The result is not significant at $p<0.05$. There is no difference between the groups.

Age of Participants Versus DDPPQ Score

Mean age of the total sample was 30.56 years (standard deviation 10.38). Mean age for doctors' group was 32.85 years (standard deviation= 11.86) and for nursing staff group was 26.59 years (standard deviation=5.21).

There is significant correlation between the age of the professional group members i.e., both doctors and nursing staff members and their respective DDPPQ scores when calculated using Pearson Product – Moment Correlation Co-efficient (2 tailed) $r = 0.29$, $n = 134$, $p = 0.00067$.



Graph 1: Distribution Graph of Age Versus Total DDPPQ Score

The graph indicates weak positive correlation between age of the participants and their corresponding DDPPQ score.

Family History versus DDPPQ Score

Participants were also asked if they had any family history of substance abuse and past history of substance abuse.

Table 3: Comparisons among Health Professional having Family History of Substance Abuse and Past History of Substance Abuse

	Response	Number of Responses	Range	Mean (Standard Deviation)	Z Score	p*Value
Family history of substance abuse	Positive	22	43-63	52.09(5.97)	-1.786	0.074
	Negative	112	24-76	49.08(9.57)		
Past history of substance abuse	Positive	23	38-65	50.17(7.16)	-0.393	0.694
	Negative	111	24-76	49.45 (9.51)		

Mann Whitney U test. * The result is significant at $p<0.05$

In Table 3, comparisons among Health professional having family history of substance abuse and past history of substance abuse are described. Using Mann- Whitney U test, we found that there is no statistical difference between the groups of health professional having past history of substance abuse and health professional who don't have past history of substance and the groups of health professional having family history of substance abuse and health professional who don't have family history of substance abuse.

A linear regression of gender, professional roles (i.e., doctors and nurses), past history of substance abuse and known history of substance abuser in the family with the principal component has not yielded any significant results.

Table 4: Health Professional Therapeutic Commitments towards Drug Abusing Patients on various Subscales of DDPPQ and total Mean Score

Subscales	Number of Questions	Mean Score Per Question (LikertScore = 1-5)	Standard Deviation
Role adequacy	8	1.99	0.65
Role Legitimacy	3	1.85	0.71
Role support	3	1.92	0.64
Work satisfaction	4	2.18	0.76
Motivation	1	3.58	1.17
Task specific Self Esteem	3	3.39	1.07
Total Score	22	49.57 (possible score 22-110)	9.13
Note: lower score denotes higher therapeutic commitment.			

Table – 4 shows a mean of total score of 49.57 (SD = 9.13) with a possible score between 22 and 110. **The diverse attitudes of Health Professionals towards substance abusers**

Table 5: Percentage of Participants in three Categories

	Frequency	Percentage
Positive [a]	36	26.86
Neutral [b]	91	67.92
Negative [c]	7	5.22
	134	100
a= Total score from 22 to 44; b) total score from 45 to 66; c) total score from 67 to 110		

The total DDPPQ scores were divided into three categories i.e. (1) Positive perception (distinctly defined perception of role), (2) Negative perception (lack of distinctly defined perception of role) and (3) neutral perception (neither distinctly defined perception of role nor lack of distinctly defined perception of role). The range for all three perceptions was determined by the possibility maximum and minimum score in 5 point- Likert scale. Table 5 shows percentage of participants in these three categories.

Discussion

Current study aimed to assess and determine the attitudes of health professionals towards patients with substance use problems in our region and to identify factors causing diverse attitudes of health professionals towards these patients. There was weak positive correlation between age of the participants and their

corresponding DDPPQ score that is older health professionals had relatively negative attitude. This was in contrast to a study that found that older nurses believed more strongly that alcoholism is an illness[14]. The two professionals' groups were assessed by comparing health professionals having family history of substance abuse and past history of substance abuse, and it was found that there is no statistical difference between the two groups of health professional. The mean DDPPQ score in these groups ranged towards lower side denoting positive attitude towards these patients, means their past or family history of substance use didn't significantly affect the attitude. Our study found that there was no statistically significant difference between the DDPPQ scores between the two groups i.e., doctors and nursing staff.

Considering all participants in a group, the lower skewed total mean DDPPQ score of 49.57 (SD = 9.13, with a possible score between 22 and 110) in our study correlated with a more positive attitude and higher therapeutic commitment to drug abusing patients. On mean Likert-format response per question (of 1= Strongly agree to 5= Strongly disagree), the highest therapeutic commitment is reflected in role legitimacy subscale which indicated the degree that professional group members felt that drug abuse history taking and counseling was a professional responsibility. Role support and Role adequacy followed the next which reflected that professional group members felt that they have adequate knowledge of drug and drug related challenges. Also whenever required, they will get support or help to resolve drug related problem. Highly skewed score in motivation and self-esteem subscale reflected lower therapeutic commitment. Role support, role adequacy, role legitimacy and work satisfaction were all somehow interconnected with each other at the basic level along with motivation and self-esteem to aid in understanding of the plight of patients of substance abuse and thereby providing therapeutic care and overall management to such patients. Our findings are in contrast to another study which found that healthcare providers struggled with the care for patients who used illicit drugs and they had less motivation, satisfaction, role support and education.[9]Crothers and Dorrian also found high scores regarding work satisfaction which indicated that nurses' attitudes regarding how much they like, and feel rewarded by, working with patients with alcohol problems, are an important determinant of the extent to which nurses are actually willing to engage in this work[15].

In an attempt to identify diverse attitudes of health professionals towards substance abusers, the sample participants were divided into three categories for ease of understanding - Positive perception, Negative perception and neutral perception; and it was found that number of healthcare professionals having neutral perception were maximum, followed by those having positive perception and least holding negative approach to the drug abuse patients. In a study nurses appeared to have, on average, attitudes that were consistently quite positive, if not neutral[14]. As healthcare professionals are the chief gatekeepers in the management of patients who suffer from substance use disorder, there is need of the hour to change both the neutral and negative attitude of the health care workers into positive attitude. To improve local services, Howard et al recommended that a training strategy should be developed with consideration to a structured programme covering all aspects of providing care to inpatients with co-occurring mental health and substance use problems; implementing training and support structures for staff will enable them to deliver more recovery and client centered interventions for patients with these co-occurring issues[10].

Healthcare delivery needs unbiased and non-judgmental attitude of healthcare professionals towards patients of substance abuse, so in an attempt to provide holistic approach and care that overlooks socio-demographic and clinical profiles, professionals should have adequate and appropriate training and exposure accordingly. We propose some ways that can be executed systematically to bring about the necessary change in the attitudes of a healthcare professional- First and foremost is sensitization of healthcare professionals (both the doctors as well as the nursing staff) which is primarily important to achieve better outcomes in management of patients of substance use disorders. Secondly, there are ways to be incorporated at the grass root level which directly and/or indirectly will have an impact on the management of such patients include: (i) training – providing education and skills to the professionals and conducting workshops at regular intervals, teaching institute – both the medical colleges and the nursing colleges are jointly responsible in training the students who take up this field and providing opportunities for them to learn,(ii) exposure – mandatory rotatory postings for every undergraduate medical/nursing student to understand patients from having them visit an addiction wing facility of outdoor and indoor patients run by the department of psychiatry at the institute where they come across such patients of substance abuse.

Conclusion

Our study found that the younger age group healthcare professionals had more positive outlook and attitude towards substance users. The lower skewed total mean score of participants denoted more positive attitude and higher therapeutic commitment. Subdivision of the participants in three groups to a step forward revealed that majority of them had either positive or neutral attitude towards patients with problem of substance abuse, leaving a minority or handful percentage of participants who had negative perception and attitude.

Implications of the Study

our study will help in identifying diverse attitude of health professional towards patients with substance use disorders and the associated factors. Awareness and proper education along with skills instilled among these healthcare professionals will strengthen the belief and trust of the patient receiving treatment and management during the prolonged period provided for deaddiction. The provision of adequate, timely guidance and motivation at every step to reduce the use of illicit substances, would help in controlling the menace of drug abuse can be well achieved.

Limitations

This was a cross sectional study with small sample size.

Future Direction

Future studies can be undertaken with large sample size to determine the changes in attitudes and knowledge of healthcare professionals prior to any kind of exposure or training received and followed up by assessing them after they have achieved skills, knowledge and training in the field of addiction psychiatry.

Abstract

Background: Attitudes and belief toward mental illnesses are important factors that affect perception of mental health. Knowing the attitude of medical students towards psychiatry and mental illnesses is of utmost importance as they are future care provider. Current study is conducted to assess the attitude of medical students towards mentally ill patients and mental illnesses, to identify correlation of attitude score with personal and family history of mental illness and, to compare the score among students of the three year-wise groups.

Method: The study population included 219 students of first, second and third professional MBBS. We designed an online data collection tool and executed it using the Google Forms. The Google Form link to the questionnaire was sent to the enrolled participants via the identified WhatsApp groups or individual number. Beliefs toward Mental Illness (BMI) scale was used to assess attitude towards mental illnesses which is a 21-item self-report measure of negative stereotypical views of mental illness. The results of the study were examined and analyzed by using Statistical Package for Social Sciences (SPSS 25.0).

Results: Out of total 21 items of the BMI scale, students showed positive attitude on majority of items. The mean score for BMI scale and per item mean score for the scale were towards positive attitude. Majority of students agree that a mentally ill person is more likely to harm others than a normal person and that mental disorders would require a much longer period of time to be cured than would other general diseases. Higher per item mean score for dangerousness and, incurability subscale showed their negative attitude. An increasing trend of positive attitude has been seen with an increase of education level and exposure towards the subject.

Conclusions: Medical students show variable scores on belief towards mental illness scale, its subscales and, individual items. Admitting this prevailing stigma needs to be acknowledged and openly discussed with medical students in order to overcome these views. Providing adequate education on mental illnesses and attached negative attitudes or myths can change these negative beliefs.

Keywords: Medical students, psychiatry, mental illnesses, stigma, dangerousness.

1. Introduction:

Attitudes and belief toward mental illnesses are important factors that affect perception of mental health. The prejudiced and negative attitudes or stigma towards people with mental illness are widespread. In our society, health professionals have similar views about those with mental health problems and mentally ill patients. Literature suggests that people diagnosed with mental illness are considered by the majority of the society as people who are dangerous, loathed, stranger and somebody whose actions cannot be predicted.[1] Globally, psychiatry as a subject, psychiatrists as professionals, and patients with psychiatric disorders are subjected to cultural stereotypes and negative attitude by the general population. What is of alarming concern is that these prejudices exist within the medical community as well.[2-6] Stigma toward mental illness is an influential factor leading to negative views among medical students toward psychiatry. Lack of knowledge and awareness about mental illnesses among the students is associated with the negative attitudes towards mental illness in the community. For medical students during their training, educational intervention targeted towards these negative attitudes may be more effective than doctors who have already completed their training because research has shown as they carry on through their career, their attitude harden and become more resistant to change.[7] The concept of iatrogenic stigma is used to describe the stigma caused or perpetuated by mental health professionals.[8] This stigma and negative attitudes can affect the quality of life for people with mental illness. There may be various reasons for this negative attitude such as lack of accurate information about mental illness and lack of contact with individuals with mental illness.[9]

While some studies have suggested that aspiring young doctors have a favorable opinion about psychiatry as a branch[10], other studies have suggested that medical students' attitude toward psychiatry is unfavorable.[11-17]

A doctor's attitude towards persons with psychiatric illness and psychiatry should involve an impression of an empathetic listener and should have non-judgmental approach. Knowing the attitude of medical students towards psychiatry and mental illnesses is of utmost importance as they are future care provider. To improve psychiatric training in this population beliefs and attitude toward psychiatric illnesses and need to be assessed and understood.

The reasons for studying the attitude specifically among medical students are that firstly as a doctor they can play an important role in decreasing negative attitude and, secondly the results from the study will help to focus strategies to change attitudes of this group. The comparison among various groups in present study will help in understanding the impact of successive undergraduate training years. The findings may help in understanding the various points of strength and lacunae in the current undergraduate curriculum regarding mental health.

Objectives:

The objectives of the current online study were-

1. To assess the attitude of medical students towards mentally ill patients and mental illnesses
2. Correlation of attitude score with personal and family history of mental illness, and
3. Comparison among students of the three year-wise groups.

2. Methodology

Study population and study area: The study population includes all the students who have

enrolled in MBBS course (first year, second year and final year) at Ananta Institute of Medical Science and Research Centre, Rajsamand, Rajasthan. Those students who will give their consent to participate in the study will be included and rests will be excluded at their will.

Study Duration: one year, June 2020 to May 2021.

Sampling techniques and sample size

Samples were obtained using stratified random sampling method. The 3 batches of medical students viz first year professional, second year professional and third year professional which were considered as strata collectively develop a sampling frame of 450 students. The minimum sample size on assumption of 95% level of significance, 5% error and 85% expected proportion was 196. After 12% adjustment of non- responders' students the final sample size was 219.

Undergraduates in the 1st year had not received formal exposure to psychiatry yet, students of 2nd year also have not attended clinical posting or lecture in psychiatry while students of Final year students had completed clinical posting and theory lectures in psychiatry. The institute is having well-functioning psychiatry department with adequate teaching staff and a good in-flow of patients in the psychiatry OPD as well as inpatient department.

Study procedure and statistical Analysis: After unlock 1.0 was announced by the Government of India from 8th of June 2020, the cases of COVID-19 were increasing all over India including Rajasthan. Hence there was risk of disease transmission by taking interview in person therefore we decided to use WhatsApp Messenger for enrolling potential participants and Google forms for filling up their response. The study was approved by institute ethics committee.

Tools: We designed an online data collection tool and executed it using the Google Forms (via docs.google.com/forms). The Google Form link to the questionnaire was sent to the enrolled participants via the identified WhatsApp groups or individual number.

Socio-demographic variables included age, gender, marital status, background, past personal history of mental illness, known history of mental illness in the family were described using descriptive statistics.

Beliefs toward Mental Illness (BMI) scale was used to assess attitude towards mental illnesses. The BMI scale is a 21-item self-report measure of negative stereotypical views of mental illness. (18) There is a total Score and the score of three sub-scales based on factor analysis: dangerousness, poor social and interpersonal skills, and incurability. There are five items in subscale dangerousness, ten items in poor interpersonal and social skills scale and six items in incurability subscale. Items are rated on a six-point Likert scale ranging from 'completely disagree' (0) to 'completely agree' (5), with higher scores reflecting more negative beliefs. In the primary validity study, Cronbach's alpha was high among American (0.89) and Asian students (0.91). The measure holds promising evidence of validity.

The results of the study were examined and analyzed by using Statistical Package for Social Sciences (SPSS 25.0). The categorical variables were described by numbers and percentages while continuous variables were described by average and standard deviation. Normality of attitude was checked using Kolmogrov-Smirnov test. After testing normality condition, the association and relationship between the variables were tested Pearson correlation by Student's t test and one way analysis of variance (ANOVA). The level of significance was considered at $P<0.05$.

3. Results

A total 219 number of students were participated in the online study. The sample comprised of 41.55% of male students and 58.44% of female students. Majority of the students were unmarried (97.26%), belonging to urban background (79.45%), having negative past personal history of psychiatric illness (86.75%) and negative family history for psychiatric illnesses (75.79%).

Table 1: Socio-demographic characteristics of respondents

Variables	Participants N (%)
Sex	
Male	**91 (41.55%)**
Female	**128 (58.44%)**
Marital Status	
Married	**6 (2.73%)**
Unmarried	**213 (97.26%)**
Place of residence	
Urban	**174 (79.45%)**
Rural	**45 (20.54%)**
MBBS Batch	
First year professional	**49 (22.37%)**
Second year professional	**138 (63.01%)**
Third year professional	**32 (14.61%)**
Had mental illness in past:	
Yes	**29 (13.24%)**
No	**190 (86.75%)**
Is someone in your family/ friends/ relative is having mental illness:	**53 (24.21%)**
Yes	**166 (75.79%)**
No	
If yes, then	
Friends	**7(13.2%)**

Relative	**20(37.73%)**

Table 1 shows socio-demographic characteristics of respondents.

Attitudes of students towards mental illness

a) Attitude by Items of the subscales

Table 2: Dangerousness subscale of BMI scale (item wise responses, percentage of participants regarding statements on the beliefs about mental illness)

Statement	**Response***					
	0	**1**	**2**	**3**	**4**	**5**
A mentally ill person is more likely to harm others than a normal person	28 (12.8%)	15 (6.8%)	36 (16.4%)	85 (38.8%)	26 (11.9%)	29 (13.2%)
	79 (36%)			140 (64%)		
Mental disorders would require a much longer period of time to be cured than would other general diseases	10 (4.6%)	8 (3.7%)	19 (8.7%)	55 (25.1%)	51 (23.3%)	76 (34.7%)
	37 (17%)			182 (83%)		
It may be a good idea to stay away from people who have psychological disorder because their behaviour is dangerous	73 (33.3%)	47 (21.5%)	41 (18.7%)	41 (18.7%)	7 (3.2%)	10 (4.6%)
	161 (74%)			58 (26%)		
Mentally ill people are more likely to be criminals	69 (31.5%)	47 (21.5%)	35 (16.0%)	45 (20.5%)	13 (5.9%)	10 (4.6%)
	151 (69%)			68 (31%)		
I am afraid of people who are suffering from psychological disorder because they may harm me	80 (36.5%)	47 (21.5%)	31 (14.2%)	50 (22.8%)	4 (1.8%)	7 (3.2%)
	158 (72%)			61 (28%)		

* Denotes 0 = Completely disagree, 1 = Largely disagree, 2 = somewhat disagree, 3 = somewhat agree, 4 = Largely agree, 5 = Completely agree

Table 2 shows item wise responses and percentage of participants regarding statements on the beliefs about mental illness on dangerousness subscale of the BMI scale

Table 3: Poor social and interpersonal skills subscale of BMI scale (item wise responses, percentage of participants regarding statements on the beliefs about mental illness)

Statement	**Response**					
	0	**1**	**2**	**3**	**4**	**5**
The term 'psychological disorder' makes me feel embarrassed	123 (56.2%)	30 (13.7%)	16 (7.3%)	24 (11.0%)	12 (5.5%)	14 (6.4%)
	169 (77%)			50 (23%)		
A person with psychological disorder should have a job with only minor responsibilities	43 (19.6%)	30 (13.7%)	49 (22.4%)	58 (26.5%)	27 (12.3%)	12 (5.5%)
	122 (56%)			97 (44%)		

I am afraid of what my boss, friends and others would think if I were diagnosed as having a psychological disorder	70 (32.0%)	24 (11.0%)	24 (11.0%)	57 (26.0%)	17 (7.8%)	27 (12.3%)
	118 (54%)			101 (46%)		
It might be difficult for mentally ill people to follow social rules such as being punctual or keeping promises	37 (16.9%)	29 (13.2%)	55 (25.1%)	38 (17.4%)	37 (16.9%)	23 (10.5%)
	121 (55%)			98 (45%)		
I would be embarrassed if people knew that I dated a person who once received psychological treatment	131 (59.8%)	29 (13.2%)	17 (7.8%)	26 (11.9%)	12 (5.5%)	4 (1.8%)
	177 (72%)			61 (28%)		
A person with psychological disorder is less likely to function well as a parent	43 (19.6%)	45 (20.5%)	35 (16.0%)	57 (26.0%)	22 (10.0%)	17 (7.8%)
	123 (56%)			96 (44%)		
I would be embarrassed if a person in my family became mentally ill	150 (68.5%)	26 (11.9%)	15 (6.8%)	13 (5.9%)	7 (3.2%)	8 (3.7%)
	191 (87%)			28 (13%)		
Mentally ill people are unlikely to be able to live by themselves because they are unable to assume responsibilities	45 (20.5%)	51 (23.3%)	50 (22.8%)	43 (19.6%)	12 (5.5%)	18 (8.2%)
	146 (67%)			73 (33%)		
Most people would not knowingly be friends with a mentally ill person	33 (15.1%)	22 (10.0%)	36 (16.4%)	62 (28.3%)	27 (12.3%)	39 (17.8%)
	91 (42%)			128 (58%)		
I would not trust the work of a mentally ill person assigned to my work team	61 (27.9%)	40 (18.3%)	44 (20.1%)	53 (24.2%)	10 (4.6%)	11 (5.0%)
	145 (66%)			74 (34%)		

0 = Completely disagree, 1 = Largely disagree, 2 = somewhat disagree, 3 = somewhat agree, 4 = Largely agree, 5 = Completely agree

Table 3 shows item wise responses and percentage of participants regarding statements on the beliefs about mental illness on poor social and interpersonal skills subscale of the BMI scale

Table 4: Incurability subscale of BMI scale (item wise responses, percentage of participants regarding statements on the beliefs about mental illness)

Statement	**Response**					
	0	**1**	**2**	**3**	**4**	**5**
Psychological disorder is recurrent	17 (7.8%)	17 (7.8%)	45 (20.5%)	77 (35.2%)	34 (15.5%)	29 (13.2%)
	79 (36%)			140 (64%)		
Individuals diagnosed as mentally ill suffer from its symptoms throughout their life	53 (24.2%)	46 (21.0%)	41 (18.7%)	53 (24.2%)	10 (4.6%)	16 (7.3%)
	140 (64%)			79 (36%)		
People who have once received psychological treatment, are likely to need further treatment in the future	19 (8.7%)	38 (17.4%)	29 (13.2%)	82 (37.4%)	29 (13.2%)	22 (10.0%)
	86 (39)			133 (61%)		
I believe that psychological disorder can never be completely cured	139 (63.5%)	19 (8.7%)	21 (9.6%)	17 (7.8%)	9 (4.1%)	14 (6.4%)
	179 (82%)			40 (18%)		
The behaviour of people who have psychological disorders is unpredictable	19 (8.7%)	24 (11.0%)	33 (15.1%)	65 (29.7%)	38 (17.4%)	40 (18.3%)
	76 (35%)			143 (65%)		
Psychological disorder is unlikely to be cured regardless of treatment	53 (24.2%)	31 (14.2%)	46 (21.0%)	46 (21.0%)	17 (7.8%)	26 (11.9%)
	130 (59%)			89 (41%)		

0 = Completely disagree, 1 = Largely disagree, 2 = somewhat disagree, 3 = somewhat agree, 4 = Largely agree, 5 = Completely agree

Table 4 shows item wise responses and percentage of participants regarding statements on the beliefs about mental illness on incurability subscale of the BMI scale

b) Attitudes by Subscale

There are five items in subscale dangerousness, ten items in poor interpersonal and social skills scale and six items in incurability subscale.

Table 5: Per item Mean and 95% CI for the three subscale and overall score of BMI scale

Subscale	**M(SD)**	**95 %CI**
Dangerousness	2.17(0.90)	2.77, 1.56
Poor interpersonal and social skills	1.77(0.92)	2.99, 0.54
Incurability	2.21(0.92)	2.94, 1.47
Full BMI scale	1.99(0.80)	4.22, -0.24

* M- Mean, SD- Standard deviation, CI- Confidence interval

Table 5 shows per item mean and 95% confidence interval for the three subscales and overall score of BMI scale.

c) Associates of attitudes

The differences in the attitude scores in different independent variables have two categories were determined by independent sample t tests. And, difference in attitude score in independent variables having more than two categories was determined by the one-way ANOVA.

As per Kolmogrov-Smirnov test statistic (D)results in 0.04762 which means that data is normally distributed. So independent sample t test has been applied to find out difference in attitude score by socio demographic characteristics.

Table 6: Difference in attitude score by socio-demographic characteristics

Characteristics	M(SD)	Diff.*(95% CI)	p-value
Sex			
Male	42.67(17.20)	1.24(-3.31,5.79)	0.59
Female	41.43(16.61)		
Marital status			
Married	60.17(9.06)	18.73(5.20,32.27)	**0.007**
Unmarried	41.43(16.72)		
Place of residence			
Urban	42.80(16.32)	4.18(-1.35, 9.71)	0.13
Rural	38.62(18.48)		
Had mental illness in past			
Yes	40.10(15.14)	2.12(-4.50, 8.74)	0.52
No	42.23(17.09)		
Is someone in your family/ friends/ relative is having mental illness:			
Yes	39.64(17.34)	3.03(-2.19, 8.27)	0.25
No	42.68(16.65)		

*Diff. =Difference in mean, (lower bound, upper bound)

Table 6 shows difference in attitude score by socio-demographic characteristics. Married students (N=6) had higher BMI score than unmarried students (N=213) and the difference was statistically significant. On further analysis it was found that of these six married students, five had positive response for history of mental illness in family, friend or any relative, also two had positive history of past mental illness. The difference among groups was not statistically significant for other characteristics.

Table 7: Difference in attitude towards mental illness by education level of students

Characteristics	M(SD)	F- value	p-value	p-value trend
Batch		9.11	**<0.0001**	**<0.0001**
I MBBS	48.11(14.34)			
II MBBS	43.63(14.71)			
III MBBS	41.08(15.21)			

*M= mean, SD= standard deviation, F=degree of freedom, p= p value

Table 6 shows that There is increase trend in positive attitude in medical students with increase in their education level ($p<0.0001$).

There was significantly positive attitude towards mental illness among III MBBS students than II MBBS and, among II MBBS than I MBBS ($p<0.0001$). An increasing trend of positive attitude has been seen with an increase of education level and exposure towards the subject.

4. Discussion

The current online study was planned to assess the attitude of medical students towards mentally ill patients and mental illnesses, to find correlations of attitude score with sociodemographic and clinical variables and, to compare the score among students of the three year-wise groups.

Out of total 21 items of the BMI scale, students showed positive attitude on majority of items (fifteen items) and negative attitude on few items (six items). The mean score for BMI scale was 41.99 and per item mean score for the scale was 1.99. This score is towards positive attitude. Jilowa et al also found in their study that Nearly 84% of second-year medical students and 52% of interns had positive attitude toward psychiatry. (19) In their study, Risal et al also found overall positive or neutral attitudes towards mental illness and psychiatry among the medical students and interns in their institute. (20)

In our study we found that majority of students agree that a mentally ill person is more likely to harm others than a normal person (64%) and that mental disorders would require a much longer period of time to be cured than would other general diseases (83%). Kodakandla et al conducted a study on Attitude of interns towards mental illness and psychiatry and found that majority of the interns believed that mentally ill person is more likely to harm others and that mental illness require a much longer time to be cured than other general diseases. (21) In our study majority (58 percent) of students agree that most people would not knowingly be friends with a mentally ill person. Jyothi NU et al also found majority (96 percent) of participants agreed with the statement. (22)

In our study we found that majority of students agree that psychological disorder is recurrent (64%), that people who have once received psychological treatment are likely to need further treatment in the future (61%), and that the behaviour of people who have psychological disorders is unpredictable (65%). Kodakandla et al also found that majority of participants (76%) believed that psychological disorder is recurrent and that the behavior of patients with psychological disorder is unpredictable (79%); two third of them (68%) were of the opinion that people who have once received psychological treatment are likely to need further treatment in the future. (21) Jyothi NU et al also found similar findings in a study on college students. (22)

Students showed per item mean score 1.77 for poor interpersonal and social skill subscale which is towards positive attitude. Higher per item mean score 2.17 for dangerousness subscale and 2.21 for incurability showed their negative attitude. In a community Study on Attitudes to and Knowledge of Mental Illness in Tehran, Ghanean H et al found that around half participants agreed that people with a mental illness “are dangerous”. (23) Contrary to our findings *Kodakandla et al* found that only one third (31%) interns believed that psychological illness is unlikely to be cured regardless of the treatment. (21)

Married students showed statistically significant higher BMI score compared to unmarried students. On further analysis it was found that of these six married students, five had positive response for history of mental illness in family, friend or any relative and, two had positive history of past mental illness. So,

these two factors might have caused higher stigma in this small sample. The attitude score was not associated statistically significantly with other sociodemographic and clinical variables.

There was significantly positive attitude towards mental illness among III MBBS students than II MBBS and, among II MBBS than I MBBS ($p<0.0001$). An increasing trend of positive attitude has been seen with an increase of education level and exposure towards the subject. Similar to our study Aruna et al also highlighted exposure to psychiatry could improve the knowledge base of medical students. (24) Tharyan et al also found that psychiatric education positively influences the attitudes of medical students towards mental illness and some aspects of psychiatry. (25) However, providing clinical training in psychiatry during under graduation seems to improve the attitude toward people with mental illness. (16, 25-27) The favorable impact of psychiatry posting on the attitude of medical students towards mentally ill has been found in previous studies from western countries. (28) Work by Mas and Hatim (2002) from Malaysia found that final year MBBS students had more favorable attitude towards mentally ill as compared to the first-year students. (29)

The National medical commission (formerly Medical Council of India) has implemented Attitude, Ethics and Communication module (AETCOM) in all medical colleges in India in August 2019. (30) The cognitive components, behavioural attitudes and ethical dimensions of AETCOM module will change the approach of future doctors to psychiatry and person with psychiatric illness. Focusing more on clinical exposure and skills the new competency based medical education (CBME) programme has increased the duration of undergraduate clinical posting to total four weeks and total 40 hours for teaching from two weeks and 25 hours pre CBME respectively. This sequential introduction of clinical posting during second professional MBBS followed by theory class and clinical posting during third MBBS part-I will be more helpful in understanding of the subject. In future, mandating psychiatry as an independent subject of examination in under graduation assessment may prove a milestone step in medical education. So, it may be expected that this increased exposure will help in removing the existing negative attitudes towards psychiatry and person with psychiatric illness.

Suggestions:

Admitting the prevailing stigma needs to be acknowledged and openly discussed with medical students in order to overcome these views. Prevailing stigma and the negative attitudes about mental illnesses affect both patient caring and psychiatry as a career choice. The development of educational strategies enabling initial interest shown during the early clinical exposure needs to be maintained. Providing public education on mental illnesses and attached negative attitudes or myths can change these negative beliefs in general public. To promote psychiatry as a career, interested students need to have increased access to an in-depth experience of psychiatry, including “enrichment activities” such as electives in psychiatry.

Conclusions:

Medical students show variable scores on belief towards mental illness scale, its subscales and, individual items. Admitting this prevailing stigma needs to be acknowledged and openly discussed with medical students in order to overcome these views. Providing adequate education on mental illnesses and attached negative attitudes or myths can change these negative beliefs.

Implications of the Study:

This study will help in understanding of belief of medical students towards mental illnesses. The comparison among various groups in

present study will help in understanding the impact of successive undergraduate training years.

Limitations:

This was a cross sectional study with small sample size.

Future Direction:

Future studies can be undertaken with large sample size to determine the changes in belief of medical students admitted year 2019 onwards.

Social Security Measures for Elderly Population in Delhi, India: Awareness, Utilization and Barriers

Community Medicine Section

CHARU KOHLI[1], KALIKA GUPTA[2], BRATATI BANERJEE[3], GOPAL KRISHNA INGLE[4]

ABSTRACT

Introduction: World population of elderly is increasing at a fast pace. The number of elderly in India has increased by 54.77% in the last 15 years. A number of social security measures have been taken by Indian government.

Aim: To assess awareness, utilization and barriers faced while utilizing social security schemes by elderly in a secondary care hospital situated in a rural area in Delhi, India.

Materials and Methods: A cross-sectional study was conducted among 360 individuals aged 60 years and above in a secondary care hospital situated in a rural area in Delhi. A pre-tested, semi-structured schedule prepared in local language was used. Data was analysed using SPSS software (version 17.0). Chi-square test was used to observe any statistical association between categorical variables. The results were considered statistically significant if p-value was less than 0.05.

Results: A majority of study subjects were females (54.2%), Hindu (89.7%), married (60.3%) and were not engaged in any occupation (82.8%). Awareness about Indira Gandhi National Old Age Pension Scheme (IGNOAPS) was present among 286 (79.4%) and Annapurna scheme in 193 (53.6%) subjects. Among 223 subjects who were below poverty line, 179 (80.3%) were aware of IGNOAPS; while, 112 (50.2%) were utilizing the scheme. There was no association of awareness with education status, occupation, religion, family type, marital status and caste ($p>0.05$). Corruption and tedious administrative formalities were major barriers reported.

Conclusion: Awareness generation, provision of information on how to approach the concerned authority for utilizing the scheme and ease of administrative procedures should be an integral part of any social security scheme or measure. In the present study, about 79.4% of elderly were aware and 45% of the eligible subjects were utilizing pension scheme. Major barriers reported in utilization of schemes were corruption and tedious administrative procedures.

Keywords: Geriatric, Pension, Rural area

INTRODUCTION

World population of elderly (people aged 60 years and above) has increased in last two decades at a pace faster than any other times before. As per World Health Organization (WHO), between 2015 and 2050, it is expected that proportion of the world's population over 60 years will double from about 12% to 22%. Similarly, the number of people aged 80 years or older will rise from 125 million to 434 million in same period [1]. India will also not be untouched by this demographic transition in coming decades. The number of elderly in India has increased by 54.77% in the last 15 years against 42.34% rise in the working population (15-59 years of age) during the same time period [2]. The proportion of the people with age more than 60 years will grow from 8% in 2010 to 19% in 2050 while the population of those aged 80 years and older will expand from 0.8% to 3%. By the year 2042, the proportion of people aged 60 years and older will exceed that of people in 0–14 year's age group in India [3].

This profound shift in the proportion of older Indians, taking place in the context of changing family relationships and limited social support system will bring with it a variety of social, economic and health care policy challenges. One direct implication of this would be increase in the prevalence of chronic conditions such as cardio vascular diseases, chronic respiratory diseases, locomotor disorders and mental disorders etc. Estimates say that nearly 45% of India's disease burden is projected to be borne by older adults in 2030, when the population age groups with high levels of chronic conditions will represent a much greater share of the total population [3].

A number of social security measures have been taken by the Indian government. The government of India came out with the National Policy for Older Persons in 1999 to promote the healthcare, financial security, nutrition, shelter, education and welfare of senior citizens in India [4].

IGNOAPS was launched in 1995 subsequently to provide monthly pension to elderly who are Below Poverty Line (BPL). In 2000, Annapurna scheme was launched which aimed at providing food security to elderly [4].

Maintenance and Welfare of Parents and Senior Citizen Act 2007 aimed to ensure need based maintenance for parents and senior citizens, protection of their rights and welfare was introduced [4]. A comprehensive National Program for Health Care of the Elderly (NPHCE) was launched subsequently in 2010 with the vision to provide accessible, affordable and high-quality long-term, comprehensive and dedicated care services to ageing population [4].

These social security measures are important and at times the only means of support for elderly. However, to assess the impact and steps for further improvement in future of such measures, it is important to have information about the level of awareness and practical problems faced by elderly while utilizing them. Therefore, this study was conducted with an objective to assess awareness, utilization and barriers faced by elderly while utilizing social security schemes in a secondary care hospital situated in a rural area in Delhi.

MATERIALS AND METHODS

This was a cross-sectional study conducted among individuals aged 60 years and above, attending a secondary level care hospital situated in a rural area in Delhi, Pooth Khurd, who gave written informed consent to participate in the study. Sample size was calculated on the basis of a previous study by Murugen PB et al., in which prevalence of awareness about social security schemes was 73.2% and that of utilization of old age pension scheme among study subjects was 73% [5]. Taking confidence interval of 95% with absolute error of 5%, the sample size was calculated to be 313. A total of 360 subjects were included in the study. These subjects were interviewed and questionnaire was filled by the investigator during each interview. Study subjects were selected by simple random sampling method.

Data was collected using a pretested semi-structured schedule, which included socio-demographic profile, awareness and utilization of various social security schemes and other measures taken by the government for the elderly, and difficulties faced in availing these schemes. Variables were decided based on the variables used in previous similar studies [2,4,5]. Pretesting was done at the secondary level hospital in rural area of Delhi among 50 elderly subjects attending medicine OPD. Accordingly, questionnaire was edited and modified. Information was also obtained about financial dependence and family support in providing care.

STATISTICAL ANALYSIS

Data was analysed using SPSS (version 17.0). Results were presented in simple proportions and means (±SD). Chi-square test was used to observe any statistical significance of difference between proportions. The results were considered statistically significant if p-value was less than 0.05.

The study was approved by the Institutional Ethics Committee of the hospital.

RESULTS

Sociodemographic Profile

As shown in [Table/Fig-1], the study sample consisted of 318 (88.3%) subjects aged 60-74 years and 33 (9.2%) in 75-84 years age group. A majority of study participants were females-195 (54.2%) and 165 (45.8%) were males. Mainly the study samples were Hindus (89.7%), married (60.3%) and were not engaged in any occupation (82.8%). Those who were residing in joint families were 260 (72.2%) while 24 (6.7%) subjects were staying alone.

A house was owned by 266 (73.9%) subjects, 86 (23.9%) were residing in a rented house and rest stayed in old age homes.

Awareness about Social Security Measures

Awareness about IGNOAPS was higher than other social security schemes as about four fifth of the subjects were aware of this as compared to about half who were aware of Annapurna scheme and only 10 (2.8%) subjects knew about senior Citizens Act. There was significant difference in awareness about Senior Citizens Act with gender (p<0.05). Subjects who were below poverty line were more aware about Annapurna scheme with 140 (62.8%) subjects knew about the same as compared to 53 (38.7%) who were above poverty line (p<0.05). A total of 294 (81.7%) subjects were aware about Indira Gandhi National Widow Pension scheme. Females (76.4%) were significantly more aware about the same as compared to males (87.9%) (p<0.05). Subjects who were widow/separated/ single or divorced were less aware (67.8%) about the same as compared to those who were married (90.8%) (p<0.05).

[Table/Fig-2] shows results when the study subjects were inquired if they were aware about other measures of support provided to them by government. A little less than half were aware about bus travel concession provided to elderly in form of bus pass. Out of 360 subjects, 41 (11.3%) subjects were not aware about such measures of government to support elderly.

Only 36 (10.0%) subjects reported that they have done savings for old age. A small number of subjects, 7 (3.6%) among females and 29 (17.6%) among males reported that they did savings for old age which was statistically significant (p<0.05). A total of 182 (50.6%) subjects said that they were dependent on their family members for their living. Higher percentage of those who were non-working (54.0%) than working (33.9%) reported that they are dependent on family (p<0.05). When asked about family support, 213 (59.2%)

Characteristic	N=360 Number (%)	Awareness about social security schemes		
		IGNOAPS N (%)	Annapurna N (%)	Senior Citizens Act N (%)
Age:				
p-value		p=0.52	p=0.4	p=0.51

Frequency distribution table.

subjects reported that their family members take care of them well while 147 (40.8%) subjects responded that their family members do not take care of them well. There was significant difference between gender where 110 (66.7%) among males and 103 (52.8%) among females said that their families take care of them well ($p<0.05$). Similarly, 90 (65.7%) subjects who were above poverty line responded that their family members take care of them well than 123 (55.2%) subjects who were below poverty line ($p<0.05$). A significantly higher number of subjects who belonged to OBC category (27.5%) agreed that they were satisfied with their lives as compared to SC/ST (4.3%) and general category (13.1%) ($p<0.05$). Noticeably, only 2 (0.6%) subjects were having health insurance to meet their health security cover.

[Table/Fig-3] shows sources of information about various social security schemes and measures taken for elderly. Most common source of information was 'local leaders' as reported by 130 (36.1%) subjects. Family and friends were the next most common sources as reported by 112 (31.1%) subjects. Television was third most common source as told by 23 (6.4%) subjects. Out of the total 360, 48 (13.3%) subjects could not remember their source of information or had no such source.

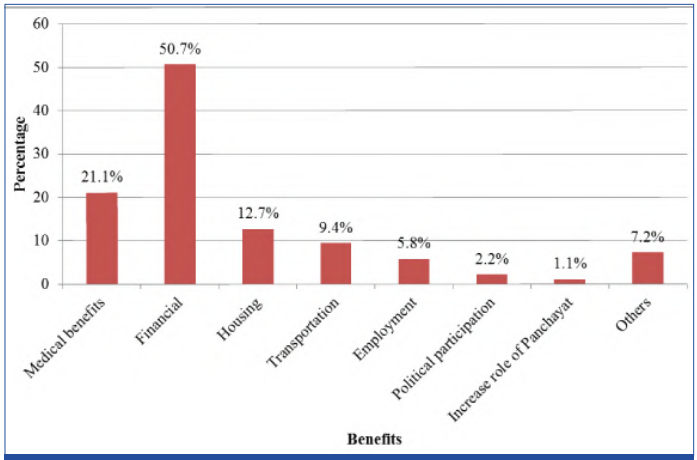
Sources of information	Number	Percentage
Local leaders	130	36.1
Family/friends	112	31.1
Television	23	6.4
Panchayat (local government members)	20	5.6
Radio	18	5.0
Hoardings	5	1.4
Posters	4	1.1

[Table/Fig-3]: Sources of information about social security schemes and measures among study subjects (n=312).
Frequency distribution table.

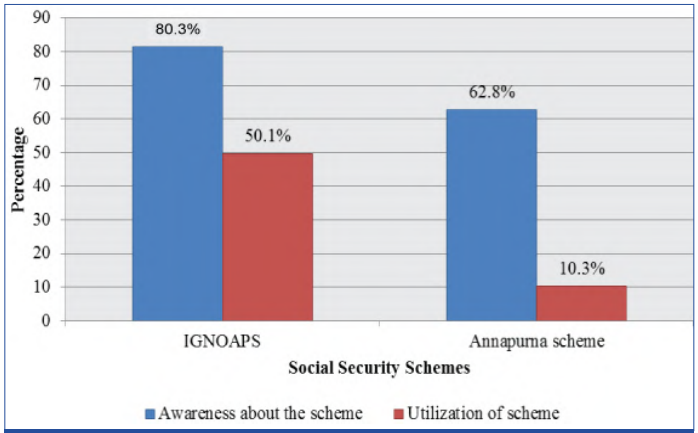
When asked about additional benefits study subjects expect from government, 76 (21.1%) subjects responded that more medical benefits, 183 (50.7%) demanded for more financial support, 46 (12.7%) said housing facilities, 34 (9.4%) expected for more transportation facilities, 21 (5.8%) asked for employment opportunities, 8 (2.2%) demanded for more political participation for them and 4 (1.1%) desired an increase in their role in local governance (panchayat) as shown in [Table/Fig-4].

Subjects below Poverty Line

Following analysis has been done only among subjects who were below poverty line and were eligible for social security schemes like IGNOAPS and Annapurna scheme. Among 223 subjects who were below poverty line, 179 (80.3%) were aware of IGNOAPS while only 112 (50.2%) of them were utilizing the scheme. Annapurna scheme was known to 140 (62.8%) subjects but only 23 (10.3%) were utilizing the same as given in [Table/Fig-5]. They were asked about the problems faced in utilization of social security schemes. The options given to the subjects were corruption, difficulty in knowing



[Table/Fig-4]: Additional benefits expected from government by study population



[Table/Fig-5]: Awareness and utilization of social security schemes among those eligible for the same among study subjects

whom and where to approach, tedious administrative formalities, other problems and no problem faced and the answers were 11.2%, 20.6%, 38.1%, 20.1% and 10% respectively. When asked if they are financially dependent on their family members, 55.2% answered yes. On probed regarding their major sources of finance, 79.4% were found to be dependent on their children and 31.8% reported that they have to borrow money from relatives often, to meet their expenses.

A high proportion of (40.8%) subjects grumbled that their family members do not take care of them well. When asked if they were satisfied with their lives, only 24 (10.8%) responded positively while 199 (89.2%) were dissatisfied with their lives.

Among below poverty line subjects, majority (87.4%) said that government has not taken adequate steps for welfare of the elderly. When enquired about the additional benefits they need from government, following responses were given – medical (18.8%), financial (57.4%), housing (13.9%), transportation (10.3%), employment opportunities (7.6%) and participation in local politics (1.3%).

DISCUSSION

The present study was conducted among 360 elderly individuals who came to seek health care services in a secondary level hospital situated in Delhi. The study population mainly comprised of subjects who were in 60-80 years age group. Hindus were found to be predominant in the study population in comparison to Muslims and Christians, which reflect the national level population structure based on religion. About half of the subjects were illiterate. Such profile was similar to the elderly profile reported by Dhanasekaran G in his study carried out in a rural area in Tamil Nadu [6].

A significant proportion of elderly were aware about IGNOAPS. It was known to 80.3% subjects and there was no association found with age, family type, caste. Lesser known than IGNOAPS

was Annapurna scheme, which was known to 53.6% subjects. Awareness was significantly higher among those who were BPL. These findings were consistent with that reported by Srivastava AK et al., in their study conducted in district Dehradun [7]. In that study, awareness of IGNOAPS was observed in 74.6% of the elderly [7]. Only 10 (2.8%) subjects knew about Senior Citizens Act, with a higher proportion of males than females were aware of the same. Bus travel concession was known to about 45% subjects but other measures like National Program for Healthcare of the elderly, interest rates etc. were known to very less subjects. This is lower than figures reported by Joseph N et al., in their study conducted in Mangalore city. The possible reasons could be higher literacy rate of subjects in that study and rural urban differentials [8].

An important finding was that despite the fact that 72.2% subjects were living in joint families, only 59% subjects replied that their family members take care of them well. There were gender differentials seen with this aspect where significantly higher number of males were taken care well by their families than females. Similarly, more literate subjects than illiterate were taken care well by families. This reflects impact of education not only in livelihood and living standard but also in social support system at household level. Such gender differentials in social support among elderly have been documented by another study also where males were more likely to be heard and involved in decision making at household level as compared to females [9].

Main sources of information were local leaders followed by family and friends. Hence, local leaders should take more steps to raise awareness about social security measures among elders in their areas and to remove barriers wherever possible. Envisioning recreation centers for elders, where they can gather together and share information with each other can prove to be an added advantage.

Major barriers reported were corruption (11.2%) and tedious administrative procedures (38.1%). This is consistent with findings of a previous mentioned study in which also bribe, procedural delay and nobody to guide were main barriers [5]. Innovative steps using information technology should be taken to make the procedure easier and to reduce the number of visits to offices for applying and tracking their applications. Corruption charges if found true should be dealt with stringent punitive actions since it deteriorates the faith of elders in system and deprive them of their rights.

Majority of subjects asked for additional financial benefits from government. The reason could be meager amount of monthly pension which is insufficient to fulfill even basic needs of a person. Insufficiency of amount has been reported by another study carried out by Nivedita BM et al., in Bengaluru as well, in which 79% subjects responded that the amount is insufficient for meeting basic needs [10]. Medical benefits were next expected need from government since health care cost of chronic illness is huge, especially in setting where majority of subjects belong to low income group. Although, government has started a separate program NPHCE for promoting geriatric health care facilities and competence among treating medical staff, the program is still in its infancy state with hardly any required infrastructure. Elderly in India are currently facing risk of dual medical problems, i.e., both communicable as well as non–communicable diseases. At present, most of the geriatric OPD services are available at tertiary care hospitals located in urban areas [11]. This tertiary care is often too expensive for people with limited income sources. As a result, those with conditions requiring tertiary care often go untreated or are left with devastating hospital bills, both of which exacerbate poverty [12]. More steps are needed by government to provide support for medical expenses for elderly population.

When analysis was done for BPL subjects who were eligible for IGNOAPS and Annapurna scheme, it was found that although 80.3% were aware of IGNOAPS only 50.2% were utilizing the scheme. This is comparable to a previously mentioned study in which 45.4% subjects were utilizing IGNOAPS [7]. Similarly, 62.8% were aware of Annapurna scheme but only 10.3% were utilizing the same. This shows a gap between awareness and actual utilization of schemes. Advertisements on mass media like television, radio, newspaper, etc., can help in increasing awareness. Corruption, difficulty in knowing whom and where to approach and tedious administrative formalities were the major barriers. Inconsistencies in identification of beneficiaries, political influence and corruption are known factors reported earlier also which poses a serious question on the implementation of this scheme [13].

LIMITATION

Firstly, the study involved subjects only from rural area. It would have been more representative of the population if elderly from urban area were also involved. Secondly, since study was conducted at secondary level hospital due to resource constraints, only those elderly patients who were coming to the hospital were included in the study. For more generalizable results, healthy elderly subjects from the residential areas also could have been included.

CONCLUSION

The present study highlights important areas of concern in providing social security for elderly population in rural area of Delhi. About 79.4% of elderly were aware and 45% of the eligible subjects were utilizing pension scheme. Awareness about other measures of social security was low. Major barriers were corruption, tedious administrative procedures and difficulty in identifying where and whom to approach for information regarding social security schemes. It is recommended that local leaders should take efforts to make elders aware of such measures. The expectations of elders for more financial security and medical benefits should be looked into in framing future polices for them. Awareness generation, provision of information on how to approach the concerned authority for utilizing the scheme and ease of administrative procedures should be an integral part of any social security scheme or measure.

Assessment of Diabetes in accordance with Indian Diabetes Risk Score (IDRS) among Adults of Delwara, Rajsamand

Mitin Parmar[1*], Milan Chaudhary[2], Pranav Bhavsar[3]
[1-3] Department of Community Medicine, Ananta Institute of Medical Sciences and Research Centre, Rajsamand, Rajasthan, India

Abstract
Introduction: Diabetes Mellitus (DM) is a metabolic disorder of multiple etiologies characterized by chronic hyperglycemia with disturbance of carbohydrate, protein and fat metabolism resulting from impaired insulin secretion, insulin action, or both. Assessment of the risk of diabetes development acts as a primary prevention measure among the high-risk population.
Objectives: To assess the risk of developing Type 2 Diabetes Mellitus using Indian Diabetic Risk Score among adults of Delwara.
Methods: A cross sectional study was undertaken among adults of age more than 30 years to assess the risk of development of DM. A pre-validated, structured questionnaire was used to assess the risk of development of DM including the Indian Diabetes Risk Score. The total scores were classified into low, medium and high-risk categories.
Results: Mean age of the study population was 46.12±10.9 yrs. Nearly 62% of study population were female, 42.7% had high school education and 44.7% were daily wage employees. Majority (47%) of the study population belonged to high risk and 36.5% belonged to medium risk category for development of DM. Increasing age, BMI, waist circumference, high Blood Pressure, a positive family history, female gender, higher education, current usage of alcohol and tobacco, sedentary to mild physical activities and high waist to height ratio were significantly associated with increased risk of development of Diabetes Mellitus.
Conclusion: The risk assessment should be put forward as a major prevention tool in the DM management.

Keywords: Risk Assessment, Delwara, Diabetes mellitus.

1. Introduction

Diabetes mellitus is a global health menace which is increasing in an alarming rate.The projected global prevalence of diabetes among adults as 9.9% by 2030 from 8.3% in 2011. While communicable diseases are slowly getting controlled in India, there is a significant increase in the burden of non-communicable diseases, including but not restricted to diabetes. The age of man-made and degenerative diseases characterized by a life expectancy close to 50-60 years and unhealthy lifestyles which promote diseases like cardiovascular disease and hypertension and Diabetes Mellitus. The prevalence rate of diabetes mellitus among the adult population ranges from 3% in rural areas to 9% in urban areas in India.

A study by the American Diabetes Association reports that India will see the greatest increase in people diagnosed with diabetes by 2030. The high incidence is attributed to a combination of genetic susceptibility plus adoption of a high-calorie, low-activity lifestyle by India's growing middle class.

Complications of Diabetes Mellitus are mainly acute complications like hypoglycemia, hyperglycemic crisis, diabetic ketoacidosis (DKA), hyperglycemic hyperosmolar state (HHS) and Chronic complications like diabetic retinopathy, diabetic nephropathy, diabetic neuropathy (micro vascular complications) macro vascular complications-cardiovascular diseases such as heart attacks, strokes and insufficiency in blood flow to legs, diabetic foot disease. Other rare complications like impaired growth and development, associated autoimmune conditions, hypothyroidism, hyperthyroidism, celiac disease, vitiligo, primary adrenal insufficiency (Addison's disease), lipodystrophy (lipoatrophy and lipohypertrophy), non-alcoholic fatty liver disease, infections seen in patients with diabetes, limited joint mobility, edema. These complications are also on the rise and contribute significantly to overall morbidity and mortality. The low levels of education and poor awareness of the disease in the country are enhancing its impact on health of the population.

While comprehensive data are not available, smaller studies have been performed in various states of India to study the prevalence of diabetes. Based on these studies, the highest prevalence reported is from Ernakulum in Kerala (19.5%) and the lowest from Kashmir valley (6.1%). Most other areas have prevalence above 10%. According to National Family Health Survey 4, the prevalence of high blood sugar level among men is 13.1% and women 8.7% in Kerala.

A majority of our population is at high risk of developing Diabetes Mellitus and is not aware of it until complications arise. Our study aims to identify these people and bring about measures to prevent the early onset of Diabetes.

2. Materials and Methods

The study was done among adults of age more than 30 years without a history of Type 2 Diabetes Mellitus at Delwara, Rajsamand, Rajasthan, INDIA during a 3 months period. Sample size of 170 was reached using the formula, $n = z^2pq/d^2$, Where, z = relative deviate (at 95% confidence interval) i.e. 1.96, p = i.e. estimated 36.5% prevalence of high risk of development of DM from a study done in Pune,

Maharashtra.
Pretested, structured interview schedule was administered to collect the data after obtaining Institutional Ethics Committee approval. The interview schedule was divided into 2 parts. The first part consisted of socio demographic details of study subjects and risk factors of diabetes. The second part was Indian Diabetic Risk Score which comprised of two modifiable (Waist circumference and Physical activity) and two non-modifiable risk factors (age and family history of T2 DM).
Indian diabetic risk score (IDRS) is the screening tool widely used to assess the risk of diabetes among general population. An IDRS ≥60 had a sensitivity of 83.8%; specificity of 81.0% in prediction of T2DM, while an IDRS <60 had a sensitivity of 79.9% and specificity of 83.8%, in prediction of non-T2DM in Indian Settings.

Operational definitions
Participants with IDRS ≥60 were considered at high risk of diabetes. Family history of diabetes If either or both of a subject's parents had diabetes, they were considered to have a positive family history. Physical activity levels were graded based on WHO STEPS definitions of sedentary, mildly, moderately or vigorously physically active. Waist circumference measured to the nearest 0.1 cm at the midpoint between the tip of the iliac crest and the last costal margin in the back and at the umbilicus in the front, using a non-stretchable tape, at the end of normal expiration, with the subject standing erect in a relaxed position. Abdominal/central obesity was considered to be present when the waist circumference was ≥80 cm in women and ≥90 cm in men. Weight was measured to the nearest 0.1 kg using a digital weight recorder. Height was measured to the nearest 0.1 cm using a wall fixed stadiometer. Body Mass Index was evaluated as weight divided by height squared (kg/m2). Waist to Height Ratio was calculated as waist circumference divided by height. The data collected was entered in Microsoft Excel and analyzed using Statistical Package for Social Sciences version 16 software. Descriptive analysis was done by calculating frequencies, proportions, mean, median, standard deviations. Chi square tests used to calculate associations.

3. Results
Mean age of the study population was 46.12±10.9 yrs. Among 170 study population 87 (51.2%) belonged to the age group of 35-49 years. Nearly 67% of study population were female, 42.7% had high school education. About 39 (23%) and 41 (24%) were currently using alcohol and tobacco respectively. Nearly 98% were following non-vegetarian diet. 32 (18.8%) of study subjects had associated hypertension and on treatment. About 58 % of study subjects have family history of Diabetes. Mean waist to height ratio was 0.61±0.11. Majority 149 (87.6%) had a high waist to height ratio. 44 (25.9%) of study subjects had raised blood pressure during the interview.
Majority (90%) had a family size <5 and nearly 62% belonged to nuclear family. About 70% of females were homemaker and 44.1% of study population was daily wagers. Nearly 56% of study population didn't have any co-morbidity. 32 (18.8%) had associated hypertension and 23 (13.5%) had osteoarthritis, 20 (11.7%) had others like asthma, stroke, Acid Peptic Disease, migraine. (Figure 1)
About 80 (47%) of the study population belonged to high risk and 36.5% belonged to medium risk category for development of Diabetes Mellitus according to Indian Diabetic Risk Score (IDRS). (Table 1)
Increasing age, BMI, waist circumference, high Blood Pressure, a positive family history and female gender had a strong association with high risk of development of diabetes. We found that higher the education higher the risk for Diabetes. Current usage of alcohol and tobacco were also associated with higher risk of development of Diabetes Mellitus. Sedentary to mild physical activities and high waist to height ratio were also associated with increased risk of development of Diabetes Mellitus.

Table 1: Indian Diabetes Risk Score

IDRS	Frequency (%)
Low Risk	28 (16.5)
Medium Risk	62 (36.5)
High Risk	80 (47)

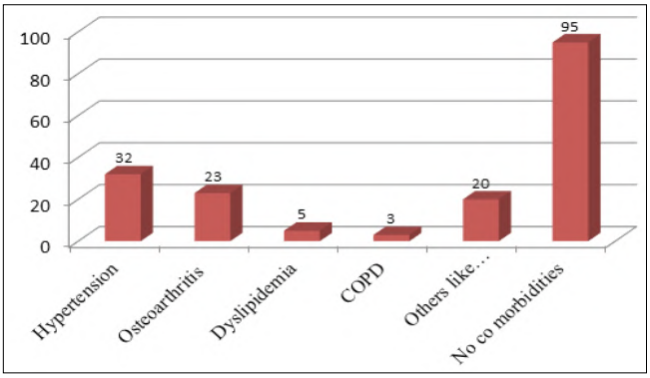

Fig 1: Associated medical conditions

4. Discussion
In this study we had found that majority of our study population belonged to age group 36-49years, nearly 62% of study population was female, 42.7% had high school education and 44.7% were daily wage employees. This was similar to a study done in Maharashtra. Using the IDRS we found that majority of 36-49 years age group belonged to moderate risk and in age group of >50, majority was under high risk of development of Type 2 Diabetes Mellitus. Many studies conducted in India showed that increasing age increases the risk of Diabetes. In another study which used Diabetes Risk Score, the age group of 55-64yrs was high risk of developing Diabetes.
In our study nearly 58% of overweight study subjects and 71% of obese people had a high risk of development of Diabetes. Studies have shown that obesity plays a major factor in the development of diabetes. Obesity and diabetes are interrelated and the term 'Diabesity' has been coined to describe the relationship between obesity and diabetes.
Another significant association was waist circumference with risk of developing Diabetes. Our study showed waist circumference and risk of developing Diabetes is directly proportionate as increased waist circumference clearly denote deposit of fat around internal organs leading to insulin resistance. Other studies showed similar results.
Among our population with high BP, about 77.3% were in the high-risk group of developing Diabetes. Diabetes damages arteries and makes them targets for hardening and atherosclerosis leading to hypertension. A population-based study done in Chennai, India among the NGT (normal glu-

cose tolerance) subjects showed about 38.2% with Hypertension came under the high-risk group of IDRS.

Apart from obesity the other risk factors for type 2 DM are age, life style factors like sedentary life style, smoking and alcohol consumption and the most important risk factor was family history of type 2 dm which has a critical role in the development of the disease which is similar to a study done in Chennai.

We did not find any significant association b/w socioeconomic status and risk of developing Diabetes. A cross-sectional study conducted at Pune, Maharashtra showed that the association between socioeconomic class and risk status was highly significant statistically (P = 0.001). We did not find any association between type of diet, occupation, family income and risk of developing Diabetes.

Every adult more than 18 years should be assessed for risk of development of Diabetes Mellitus using IDRS or any other simple tool. It will not just aid in early detection and prevention of complication of Type 2 DM but also helps to reduce the morbidity and mortality associated with it. This tool can be used as a primary prevention measure to motivate people against metabolic diseases and cardiovascular diseases. As majority of study population belonged to high and moderate risk for development of Diabetes, urgent follow up and health education are needed in the area with a Random Blood Sugar testing for all followed up by definitive diagnostic tests. Development of comprehensive health approaches including dietary and lifestyle modifications and awareness regarding the risk of Diabetes Mellitus and its complications should be done.

The assessment of risk would have been complete if qualitative component also added. That would have shed a light regarding the resistance towards adapting the healthy lifestyle.

5. Conclusion

Majority (47%) of the study population belonged to high risk and 36.5% belonged to moderate risk category for development of Diabetes Mellitus. Increasing age, BMI, waist circumference, high Blood Pressure, a positive family history and female gender had a strong association with high risk of development of diabetes. We found that higher the education higher the risk for Diabetes. Current usage of alcohol and tobacco were also associated with higher risk of development of Diabetes Mellitus. Sedentary to mild physical activities and high waist to height ratio were also associated with increased risk of development of Diabetes Mellitus.

Abstract

Background: Pre-hypertension is associated with an increased risk of the development of hypertension and subsequent cardiovascular disease and raises mortality risk. Pre-hypertension is emerging health problem in adolescents now a days. The aim of this study was to determine the prevalence of pre-hypertension, to explore the association between pre-hypertension and established cardiovascular risk factors and compare them among second year and final year students of AIMS & RC, Rajsamand.

Methods: In this cross-sectional study a representative sample of 200 participants was selected using a Random sampling method. Pre-hypertension was observed among 73 out of Total 200 students, 31 from second year and 42 final year students, 40 for Boys and 33 for Girls.

Result: The pre-hypertensive group had higher body mass index, higher percentage of smoking, ate more added salt and less physical activity than did the normotensive group. Prevalence of prehypertension was higher among final year students than second year students due to heavy study stress.

Conclusion: Primary prevention strategies should concentrate on reducing overweight and obesity. Diet education should be given to overcome this problem. Stress is another major predictor in medical students so Medical authority should make some strategies to relieve stress in medical students.

Introduction:-

The global burden of non-communicable diseases is emerging as a major public health challenge in the world. One thing is clear: "when it comes to NCDs, inaction is not an option." According to WHO, chronic disease is modern epidemic. 60% of all deaths and 47% of burden of diseases are due to non-communicable diseases; these figures are expected to rise to 73% and 60%, respectively, by 2025. Hypertension is a well-known risk factor for the development of CVD, heart attack, and stroke. Hypertension is responsible for 57% of stroke deaths and 24% of coronary heart disease deaths in India. Due to change in life style, environmental and Socio-demographic risk factors the prevalence of Pre-hypertension and hypertension is increasing constantly. Pre-hypertension is associated with an increased risk of the development of hypertension and subsequent cardiovascular disease and raises mortality risk. Persons with pre-hypertension have a greater risk of developing hypertension than do those with lower blood pressure levels. Pre-hypertension is also an emerging health problem in adults and adolescents now a day. Medical Students are more prone to be exposed with established cardiovascular risk factors.

Corresponding Author:- Mitin Parmar

Aims:
The study was aimed to know the prevalence of Pre-hypertension and its determinants in Second year and Final year students of AIMS & RC, Rajsamand and compare them.

Objectives:-

1. To determine the prevalence of pre-hypertension
2. To explore the association between pre-hypertension and established cardiovascular risk factors
3. Compare those risk factors among a second year and final year students of AIMS & RC, Rajsamand

.

Methodology:-

Sample Size: Prevalence of pre-hypertension was 34% in various studies among adolescents and adults. Sample size was calculated by the Following formula.

Sample Size (N) = $4pq/L^2$
Where, p = Prevalence of pre-hypertension=34%
q = 100-p = 66%
L = 20% of p = 6.8
So Sample size (N) = 4*34*66/46.51

The estimated sample size was 193. Sample size of 200 was decided.100 students from second year and 100 students from final year.

Study design:
In this cross-sectional study, Participants were selected using a Random sampling method. (Chit method)

Study Area:
AIMS & RC, Rajsamand

Study Population:
Second year and Final year students of AIMS & RC, Rajsamand.

Data collection:
All Students were interviewed with predesigned questionnaire.

Blood pressure was measured after the students had rested for at least 5 minutes and from right arm placed at the heart level. Two measurements were taken by a mercury sphygmomanometer with at least 5 minutes between successive measurements and lower one was recorded. According to the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and treatment of High Blood Pressure (JNC 7) in 2003, prehypertension is defined as blood pressure range with a systolic BP of 120–139 millimeters of mercury (mmHg) and/or a diastolic BP of 80–89 mmHg. Body weight was measured with light cloth and without shoes, a common weighing machine was used for that.

Height was measured to the nearest 0.5 cm, without shoes using a measuring tape

Body mass index (BMI) was calculated as weight (in kilograms) divided by height (in meters) squared.

Data Analysis:
Statistical analysis was performed using Microsoft excel and EPI INFO version 7 software.

Results:-

Pre-hypertension was observed among 73 (36.5%) out of 200 students, 34 (34%) from second year and 42 (42%) final year students while 5(5%) were hypertensive in second year and 8(8%) in final year.

Table 1:- Presence of different risk factors among Normotensive and Pre-hypertensive SECOND YEAR Students.

Risk Factors	Normotensive	Pre-hypertensive	P

	(61) (61%)	(34) (34%)	value
Family history of hypertension	11 (18.32%)	6 (17.64%)	0.9643
Stress Factor	10 (16.39%)	8 (23.52%)	0.3948
Male sex	37 (60.65%)	18 (52.94%)	0.4653
Excessive salt intake	30 (45.45%)	19 (55.88%	0.5307
Smoking	14 (21.21%)	9 (26.47%)	0.7014
Lack of physical activity	24 (36.36%)	16 (47.05%)	0.4653
Overweight/obese	32 (48.48%)	19 (55.88%)	0.7482

Table 1 showing different risk present among second year students of AIMS & RC. Male sex, excessive salt intake and overweight and obese were major risk factors which were observed in second year students AIMS & RC, Rajsamand.

Table 2:- Presence of different risk factors among Normotensive and Pre-hypertensive FINAL YEAR Students.

Risk Factors	Normotensive (50) (50%)	Pre-hypertensive (42) (42%)	P value
Family history of hypertension	12 (24%)	10 (23.80%)	0.8301
Stress Factor	09 (18%)	17 (40.47%)	0.017
Male sex	27 (54%)	24 (57.14%)	0.7629
Excessive salt intake	21 (42%)	22 (52.38%)	0.3202
Smoking	11 (22%)	11 (26.19%)	0.6390
Lack of physical activity	19 (38%)	18 (42.85%)	0.6390
Overweight/obese	22 (44%)	26 (61.90%)	0.08

Table 2 Showing different risk present among final year students of AIMS & RC. Major risk factors which were observe in final year students were almost same as in second year students of AIMS & RC, Rajsamand

Table 3:- Association of Pre-hypertension with Stress.

Year	Total Pre-hypertensive Students	Pre-hypertensive Students With Stress
Second Year	34	8(23.52%)
Final Year	42	17(40.47%)

Second Year: chi squire value 0.401, df =1, P=0.52657 (P>0.05), Test is not significant.
Final Year: chi squire value 5.591, df =1, P=0.018059 (p<0.05), Test is significant.

Discussion:-

The pre-hypertensive group had higher body mass index, higher percentage of smoking, ate more added salt and less physical activity than did the normotensive group. (Table 1)

(Table 2) These findings are consonant with previous reports on risk factors in pre-hypertension for cardiovascular disease[8]. Prevalence of pre-hypertension was higher among final year students than second year students may be due to heavy study stress. Analysis showed that Stress is major risk factor to developing Pre-hypertension and also hypertension. (Table 3)

Analysis showed that obesity and overweight were the strongest predictors of pre-hypertension.

Conclusions:-

Overweight and obesity are major determinants of the high prevalence rate of pre-hypertension detected in students of AIMS & RC, Rajsamand. Therefore, primary prevention strategies should concentrate on reducing overweight and obesity. Diet education should be given to overcome this problem.

Stress is another major predictor in Final Year medical students so Medical authority should make some strategies to relieve stress in medical students.

The normotensive Group also having higher percentage of these risk factors so they are also prone to develop pre hypertension in future. so preventive step should take in Normotensive students like health education.

Nocturnal enuresis-prevalence and risk factors among school going children in Udaipur, Rajasthan, India

Neeta Mishra and Achchhadita Mishra

DOI: https://doi.org/10.33545/comed.2020.v3.i1b.123

Abstract
Background: Nocturnal Enuresis also called bedwetting is involuntary urination while asleep after the age at which bladder control starts developing in children. Nocturnal Enuresis is a common problem affecting school aged children worldwide. It can cause a feeling of failure and result in guilt and stress in children as well as in their families.
Aims and Objective: To find out prevalence and underlying its risk factors in the age group of 6-16 years.
Material and Methods: It is a population-based study conducted during the year June2018 to January 2019 on 328 children in the age group of 6 to 16 years residing at Neemachmata area of urban Udaipur (Raj.).
Result: The study was conducted on 328 children aged between 6 to 16 years. The prevalence of enuresis was 17.37% There was a significant relationship between the prevalence of enuresis and age, sleep pattern, as well as high intake of substances like tea, coffee &soda. Stress and positive family history of bedwetting also affect the prevalence. Highest number of enuretics were found in the age group of 6 to 8 years (32.14%) out of total numbers of enuretics (57). 28 (17.7%) were male & 29(17.05) females. This show that nocturnal enuresis was common in both the sexes. Lowest number of enuretics were found in the age group of 15 to 16 years of age. Number of enuretics were found to be higher in modified B.G. Prasad socio-economic class IV & least in socio-economic class II. Positive family history was present in 36 (37.50%) out of 57 enuretic children.

Keywords: Prevalence, nocturnal enuresis, risk factors

Introduction
Nocturnal enuresis affects approximately 5-7 million children in USA and 9-13% children in India. It's a common problem in pediatric patients. Inspite of the causative factors are not well-established resulting in depression (low self-esteem) & school withdrawal among children and stressed parents appropriate intervention is justified for the affected child because of the potential consequences of family stress, social withdrawal and poor self-esteem [1].
Enuresis refers to the persistence of inappropriate voiding of urine beyond the age of anticipated bladder control (age 4 to 5 years at the latest) or as the loss of continence after at least 3 months of dryness. The diagnosis is made when wetting occurs twice a week for 3 consecutive months [2].
Enuresis may be further classified into nocturnal & diurnal [2].
Aims & objective Aim of this study was to find out the prevalence & underlying its risk factors in the age groups 6-16 years.

Material and Methods
It is a population-based study was conducted on 328 children in the age group of 6 to 16 years residing at Neemachmata area of urban Udaipur Data were collected via a questionnaire completed by parents after taking consent and collected from door to door personally. The relationship has been found between the prevalence of Enuresis and the patient's age, gender, family history, sleep pattern, and use of tea, coffee, soda and the education level and employment status of parents and their monthly income. These findings were tested by means of X^2 test and $P< 0.05$ was accepted as statistically significant.

Ethical clearance

Clearance from Institutional Ethics Committee was taken before start of study.

Result

The study was conducted on 328 children aged between 6 to 16 years. Chi square test was used and we found the prevalence of enuresis was 17.37%. Relationship was formed between the prevalence of Enuresis and age, positive family history, sleep pattern, intake of tea, coffee, soda and stress. In the whole group enuresis was found to be equally common in both the sexes. No relationship was found with family size, Parents education level and employment.

The prevalence rate of nocturnal enuresis in our study was (17.37%) Highest number of enuretics were found in the age group of 6 to 8 years (32.14%) out of total numbers of enuretics (57). 28 (17.7%) were male & 29(17.05) females. This show that nocturnal enuresis was equally common in both the sexes. Lowest number of enuretics were found in the age group of 15 to 16 years of age.

Number of enuretics were more in modified B.G. Prasad socio-economic class IV & least in socio-economic class II. Positive family history was present in 36 (37.50%) out of 57 enuretic children.

Discussion

In this study, the prevalence rate of nocturnal enuresis is (17.37%) almost comparable with that reported in epidemiological studies from various countries [3, 6].

The prevalence of enuresis showed a decreasing trend in older children's [3].

This study showed no gender differences in prevalence rate. Supported by the other study [6].

Conclusion

Our findings suggest that nocturnal enuresis was a common problem among school children especially with low income, stress, and deep sleep pattern, higher intake of tea, coffee, soda, and family history of enuresis.

Enuresis is a common pediatric problem and resulting in low school performance. The preventive, etiological, psychological & curative measures has be taken. We conclude that nocturnal enuresis is more common in the age groups of 6–8 years & it is found higher in families with B.G. Prasad socio-economic class IV.

It is a self-limiting problem with a spontaneous cure rate of 14% per year in children 5- 9 years old and 16% per year in adolescents.

ABSTRACT

Background: Biomedical waste defined as any waste which is generated during the diagnosing, treating, and surgical intervention and immunizing and also conducting research activities on humans as well as on animals. Health care facilities are aimed to provide health care services to the general population to remove potential health hazards to people. **Material & Methods:** The present observational, prospective and cross-sectional study was conducted at the Department of Community Medicine of our medical college and hospital. The study duration was of six months, from May 2017 to October 2017. We include the nursing staff of our medical college along with two other hospitals of Rajsamand district, Rajasthan in the present study. Clearance from Institutional Ethics Committee was taken before the start of the study. **Results:** In the knowledge domain 51% of study participants answered Correct response on color-coded bags with respective waste and 77% of study participants answered Correct response on knowledge about colour coded bags. In the attitude domain, 94% of study participants had a positive attitude towards bio-medical waste (BMW) management categorization needs and 96% of study participants had a positive attitude towards bio-medical waste management necessary and reduction of health hazard. In the practice domain, 62% of study participants show a positive response towards disinfecting bio-medical waste (BMW) and 70% of study participants had a positive response towards the bio-medical waste treatment. **Conclusion:** We concluded from the present study that nursing staff had good knowledge and had a positive attitude towards biomedical waste management and positive findings towards practices related to BMW. However there still a knowledge attitude and practice gap exit. Therefore, the training programs for the nursing staff should be necessary to reduce this KAP gap related to biomedical waste management.

Keywords: Bio-medical waste management, knowledge, attitude, practice.

INTRODUCTION

Biomedical waste defined as any waste which is generated during the diagnosing, treating, and surgical intervention and immunizing and also conducting research activities on humans as well as on animals. Health care facilities are aimed to provide quality health care services to the general population and to remove potential health hazards of people **(1)**. During the processes of health care methods in health care facilities various wastes are generated, these wastes are hazardous to the general population. If these health care facilities generated waste (Biomedical waste) is handled poorly, it can be a potential health hazard for not only the general population but also to the health care providers,

doctors, nurses and all other health care and other hospital staff which are exposed to these biomedical wastes. Apart from humans, these biomedical wastes are highly hazardous to the environment, water bodies, groundwater, air and community, and animals. Some previous studies reported that developed countries generate more biomedical waste than developing and underdeveloped countries **(2)**.

Various studies reported that out of total waste generated in the health care facilities 90-85% volume of that waste is non-infectious or no hazardous. It means only 10-15% of the total waste generated in the health care facilities is infectious or hazardous which includes toxic or radioactive waste also. Therefore, the first and most important step of biomedical waste management should be the segregation of the total waste generated in the health care facilities. By the proper segregation of waste, we can reduce the volume of infectious waste from 100% to 15% by interrupting the mixing of non-hazardous waste to infectious or hazardous waste **(3)**. Hence, we have new guidelines for biomedical waste which allow us to segregate the total waste generated in the health care facilities in different colour coded bins, containers, and bags. In the disposal of total waste generated in the health care facilities, we use only non-chlorinated bags for safer disposal in the environment **(4)**. Workers who are engaged in the laundries, transportation of the waste and workers at the landfilling site are also at risk for hazardous exposure of biomedical waste. We conduct the present study to assess the knowledge, attitude, and practices of biomedical waste management among nursing staff of Rajsamand district, Rajasthan.

MATERIALS & METHODS

The present observational, prospective and cross-sectional study was conducted at the Department of Community Medicine of our medical college and hospital. The study duration was of six months, from May 2017 to October 2017. We included the nursing staff of our medical college along with two other hospitals of Rajsamand district, Rajasthan in the present study. We enrolled study participants by the simple random sampling up to the study sample size of 100 participants calculated by epi info software at a 95% confidence interval and 10% acceptable margin of error. Clearance from Institutional Ethics Committee was taken before the start of the study and written informed consent for the study purpose was obtained from all the enrolled participants.

The study was performed by using pretested and semi-structured proforma. The data collected from each study participants includes details of all the various demographic variables and details regarding knowledge, attitude, and practices for biomedical waste handling and its management. Knowledge, attitude, and practices were evaluated on correct and wrong responses. Data were entered in the MS office 2010 spreadsheet and Epi Info v7. Data analysis was carried out using SPSS v22. Qualitative data were expressed as the percentage (%) and Pearson's chi-square test was used to find out statistical differences between the study groups. If the expected cell count was < 5 in more than 20% of the cells then Fisher's exact test was used. All tests were done at alpha (level significance) of 5%; means a significant association present if the p-value was less than 0.05.

RESULTS

In the present study, a total of 100 nursing staff were enrolled after taking informed written consent, who were nursing staff of our medical college along with two other hospitals of Rajsamand district, Rajasthan. Out of the total study participants, 58% were males and 42% were females. The age group of study participants was ranged from 23 years to 27 years with a mean age group of 24.8 ± 1.2 years. Among the total study participants, on the assessment of knowledge we found that 76% of study participants had knowledge about disease occurring from biomedical wastes, 77% study participants had knowledge about colour coding of BMW bags, 70% study participants had knowledge about steps of disposal of biomedical waste and 73% study participants had knowledge about biohazard symbol. (Table 1)

Table 1: Distribution according to the knowledge of study participants.

Knowledge	No. of participants (%)
Diseases from BMW	76
Colour coded bags	77
Steps of disposal	70
Biohazard symbol	73

In the present study among the total study participants on the application of knowledge, attitude and practice domains we found that after

analysis that in the knowledge domain 51% of study participants answered correct response on colour coded bags with respective waste and 77% of study participants answered correct response on knowledge about colour coded bags. In the attitude domain, 94% of study participants had a positive attitude towards bio-medical waste (BMW) management categorization needs and 96% of study participants had a positive attitude towards bio-medical waste management necessary and reduction of health hazard. In the practice domain, 62% of study participants show a positive response towards disinfecting bio-medical waste (BMW) and 70% of study participants had a positive response towards the bio-medical waste treatment. (Table 2)

DISCUSSION

In the present study, a total of 100 nursing staff were enrolled in our medical college along with two other hospitals in Rajsamand district, Rajasthan. Out of the total study participants, 58% were males and 42% were females. The age group of study participants was ranged from 23 years to 27 years with a mean age group of 24.8 ± 1.2 years. Among the total study participants, on the assessment of knowledge we found that 76% of study participants had knowledge about disease occurring from biomedical wastes, 77% study participants had knowledge about colour coding of BMW bags, 70% study participants had knowledge about steps of disposal of biomedical waste and 73% study participants had knowledge about biohazard symbol. Similar results are found in a study conducted by Kaviraj Motakpalli et al among the students of nursing in their study and found nearly similar results to the present study. They reported higher knowledge ranging from 77% - 97% on the biomedical waste management and also were higher attitude and practice response **(5)**. Similar results are found in a study conducted by Prachi Priya et al among the students of interns of the medical college in their study and found nearly similar results to the present study. They reported higher knowledge ranging from 86% - 94% on biomedical waste management and also higher attitude and practice response **(6)**.

In the present study among the total study participants on the application of knowledge, attitude and practice domains we found that after analysis that in the knowledge domain 51% of study participants answered correct response on colour coded bags with respective waste and 77% of study participants answered correct response on knowledge about colour coded bags. In the attitude domain, 94% of study participants had a positive attitude towards bio-medical waste (BMW) management categorization needs and 96% of study participants had a positive attitude towards bio-medical waste management necessary and reduction of health hazard. In the practice domain, 62% of study participants show a positive response towards disinfecting bio-medical waste (BMW) and 70% of study participants had a positive response towards the bio-medical waste treatment. Similar results are found in a study conducted by Aastha Pandey et al among the students of interns of the medical college in their study and found nearly similar results to the present study. They reported higher knowledge ranging from 68% - 94% on biomedical waste management and also higher attitude and practice response **(7)**.

Contrary results were found in a study conducted by S Shah et al among the students of interns of the medical college in their study and found nearly contrary results to the present study. They reported poor knowledge of intern doctors on biomedical waste management and also poor attitude and practice response **(8)**. Contrary results were found in a study conducted by Kirti Deshpande et al among the health care staff of tertiary care centre in their

study and found nearly contrary results to the present study. They reported poor knowledge of health care staff of tertiary care centre on the biomedical waste management and also poor attitude and practice response **(9)**.

CONCLUSION

We concluded from the present study that nursing staff of our medical college along with two other hospitals of Rajsamand district, Rajasthan had good knowledge and had a positive attitude towards biomedical waste management and positive findings towards practices related to BMW. However, there is still a knowledge attitude and practice gap exit. Therefore, the training programs for the nursing staff should be necessary to reduce this KAP gap related to biomedical waste management.

Abstract

Introduction: Coexistence of diabetes and depression, stress and anxiety increase the risk of diabetes complications and reduces the overall quality of life. **Objectives:** To assess the prevalence of depression, stress and anxiety among patients with type 2 diabetes mellitus attending a community-based and peer-led life style modification setting.**Materials and methods**: Descriptive study was carried out among 145 purposively selected clinically diagnosed type 2 diabetics attending community-based and peer-led life style modification setting from February 2019 to July 2019. Patients were interviewed regarding depression, stress and anxiety using the Patient Health Questionnaire-9 (PHQ- 9) and Generalized Anxiety Disorders-7 (GAD-7) and Cohen's perceived stress scale (PSS-10). Data were analysed using coGuide software. The level of statistical significance assumed in all the calculations was $p<0.05$.**Results:**The mean age was 52.39± 5.79 years with equal proportion of males 73 (50.34%) and females 72 (49.66%). The mean duration of diabetes was 7.41± 6.39 years. The Cohen perceived stress score was low in 27(18.62%),moderate in 101(69.66%) and high in17(11.72%) participants. The GAD-7 anxiety score was mild in 55 (37.93%),moderate in 31 (21.38%)and high in 17(11.72%) participants. The PHQ score was mild in 42(28.97%) and was severe in only 8(5.52%) participants. The association of depression, stress and anxiety was significant only for gender *(p* -value of 0.006).**Conclusion:**Prevalence of depression, stress and anxiety was mild to moderate among patients with type 2 diabetes mellitus attending a community-based life style modification setting

Keywords: Diabetes, Type II diabetes mellitus, Depression, Anxiety, Stress

Introduction

Diabetes is a lifelong journey that results in fundamental changes in the patients' lifestyles and may cause increased psychological anxiety and distress, financial burdens, and adverse health effects [1]. The number of people with diabetes in India has been projected to increase to 109 million by 2035. Diabetes is associated with an increased risk of both physical and psychological complications, both of which impact on mortality. Depression, stress and anxiety are highly prevalent psychological disorders in the diabetic population[2].It was estimated that diabetic patients have at least twice the risk of depression or anxiety that is associated with increased risk of comorbidities, interference with daily activities and quality of life, higher health care costs, and more complications when compared to normal patients[3]. Worldwide estimates of the prevalence of depression and anxiety among diabetic patients appear to vary by nations; though data is scarce from developing countries, studies from Asia (including India) report prevalence rates of depression ranging from 17% to 44% and for anxiety it is from 4% to 58%[4]. A recent meta-analysis of 16 studies[5] had revealed analarming significant association between depression and increased risk of mortality (odds ratio, OR = 1.5) in patients with diabetes.Stress is a nonspecific bodily response to any demand made upon it. As adherence to various self-management practices is the cornerstone of daily management of type 2 diabetes, perceived stress could negatively impact the long-term health outcomes of the affected individuals[6]. Stressful life events are, however, prone to happen and it is important to identify how perceived stress impacts blood glucose levels, of individuals with diabetes using perceived stress scale by Cohen's[7].Depression has been recognized as a common comorbidity in patients with type 2 diabetes associated with poor glycaemic control, functional impairment, increased risk of diabetic complications and mortality, and reduced societal productivity[8]. The 9-item Patient Health Questionnaire (PHQ-9) is one of the most popular self-administered screening tools that has been validated in many populations[9].There are many previous individual studies reported by Thour et al[2] ,Wolfgram et al[10]and Wiernik et al[11] that hypothesized the association of stress, depression and anxiety on diabetes using these screening tools. In another cross-sectional study among adult patients with T2DM in five public primary care centres in the western region of Saudi Arabia by Alzahrani A et al [12]the prevalence of depression, anxiety, and stress were 33.8%, 38.3%, and 25.5%, respectively and the major predictors of psychological distress were age, sex, the presence of comorbidities, duration since T2DM diagnosis, and serum level of hemoglobin A1c. Another study by Gupta Y et al[13]from India reported the prevalence of depression as

E-mail:dr.rohini@beyondpvalue.com

41% using (PHQ score ≥15).Depression was significantly more prevalent in rural subjects (57%) when compared to urban ones (31%, *P* = 0.049). Due to varying prevalence rate of diabetes as well as depression and anxiety from various parts of India, the exact disease burden still remains unclear. The prevalence of comorbid diabetes, depression and anxiety is limited in India.This study adds to the limited available information on the prevalence of anxiety, stress and depression checked using screening tools among diabetics inIndia. To the best of our knowledge, the utility of generalized anxiety disorders 7-item (GAD-7) scale, Patient Health Questionnaire (PHQ-9) and Perceived stress scale by Cohen's has been evaluated for the first time in India to study this association. This data will be helpful for the healthcare providers to plan collaborative care in healthcare settings.

Aims and objectives

To assess the prevalence of depression, stress and anxiety among type 2 diabetics attending a community-based peer- led lifestyle modification setting.

Materials and methods

Study design

A descriptive cross-sectional study

Source population

Subjects attending a community-based lifestyle modification setting

Study population

Subjects diagnosed with type 2 diabetes and attending a community-based lifestyle modification setting.

Study setting

The study was conducted at a community centre.

Study period

For a period of 6 months from February 2019 to July 2019

Sample size and sampling technique

All 145 patients with type 2 diabetes mellitus attending the lifestyle modification centre were selected according to convenience sampling for the feasibility of the study**.**

Ethical and informed consent

Prior permission was obtained from ethical members of the community centre and written informed consent was taken from all the subjects before the study started. Confidentiality was maintained all along.

Inclusion criteria

- Both male and females aged 18-60 years.
- Subjects who can comprehend the questionnaire
- At least diabetic since a year and on medication

Exclusion criteria

- Previous clinical diagnosis of anxiety, depression, and other psychiatric disorder**.**
- Taking drugs like–sedatives,glucocorticoids, and immune osuppressive
- Not receiving any psychiatric treatment which could have an effect on the result.

Data collection

The psychological assessment was carried under a team of data collectors who were trained in the questionnaire (GAD-7, PHQ-9, PSS-10). Prior permissions were obtained from all the originators of the questionnaires to use them in this study.

Generalized anxiety disorder

The GAD- 7 scale was used for evaluation of anxiety, and relevant clinical details were obtained. Anxiety was assessed by administering the GAD-7 scale. This scale is useful for evaluating the presence and severity of GAD in clinical practice. This tool has several advantages. First, a 7-item anxiety scale - the GAD-7 - is a useful tool with strong criterion validity for identifying probable cases of GAD. Second, the scale is also an excellent severity measure as increasing scores on the GAD-7 are strongly associated with multiple domains of functional impairment and disability days. Third, although many patients had anxiety and depressive symptoms, factor analysis confirms GAD and depression as distinct dimensions, GAD-7 measuring GAD with high sensitivity and specificity with appropriate cut-offs. It assesses the symptoms experienced by participants during the 2-week period before they take the survey. On the basis of participant response to the frequency of any particular symptom (0 = not at all, 1 = several days, 2 = more than half of the days, and 3 = nearly every day), a total score ranging from 0 to 21 was obtained, with higher scores indicating patients increased self-report of anxiety severity. The division of GAD-7 scores into ratings of mild (5-9), moderate (10-14), and severe anxiety (≥15) was used in this study[14].

Cohen's perceived stress scale

The PSS-10, (Cohen et al.,1983) measures an individual's appraisal of their life as stressful (i.e., unpredictable, uncontrollable and overloading). Item examples include, 'How often have you felt nervous or stressed?' and 'How often have you felt confident about your ability to handle your personal problems?' People rated how often they had experienced these feelings in the last week on a Likert scale from 0 = never to 4 = very often. PSS-10 scores were obtained by reversing the scores on the four positive items; the items were 4, 5, 7 and 8. Total scores range from 0 to 40, with higher scores indicating greater overall distress. Coefficient alpha reliability was 0.86 for a newly diagnosed breast cancer population consistent with alphas from 0.75 to 0.86 in the general literature (Cohen et al., 1983)[7].

Patient health questionnaire

The PHQ-9 is derived from the DSM-IV diagnostic criteria, and consists of 9 questions pertaining to the frequency of depressive symptoms during the preceding two weeks. Each item is scored from 0 (not at all) to 3 (nearly every day), with a total score ranging from 0 to 27. Cut-off values of 5, 10, 15 and 20 have been widely used to define mild, moderate, moderately severe, and severe depressive symptoms (Kroenke et al., 2001)[9].

Investigations:The values of the glucose measures – HbA1c and systolic blood pressure and diastolic blood pressure were measured. Next, questionnaire studies were carried out which was accompanied by brief information such as: age, sex, place of residence, education, marital status, professional activity, body mass, height, used stimulants, comorbidities, the duration of diabetes, the occurrence of diabetes complications and the taken drugs.

The questionnaire was filled in personally and anonymously by the patients.

Life style modification centre

The study was an inpatient holistic intervention conducted in Nadiad and Bhavnagar in Gujarat.Vegetarian diet, daily practice of Raja Yoga Meditation, attending daily class on positive thoughts, avoidance of tobacco, refraining from consumption of alcohol or any harmful substances, along with the associated beliefs listed above, form a part of "Brahma Kumari's Raja Yogi Lifestyle". The patient after screening for inclusion and exclusion criteria were taken for the study. 4 camps were conducted.

Study variables

Prevalence of depression, stress and anxiety were considered as dependent or primary outcome variables. Age, sex, marital status, residence, religion, level of education, duration of diabetes, having diabetic complications, smoking status, status of alcohol consumption, comorbidities were considered as independent variables.

Statistical analysis: The statistical analysis was performed using the coGuide software. The level of statistical significance assumed in all the calculations was $p<0.05$. Basic statistics, i.e., the mean and the standard deviation were calculated for quantitative data. The Chi-square test were used for checking the occurrence of relationships between the considered variables. The reliability of the applied questionnaires was checked by calculating the Cronbach's alpha coefficient (> 0.7 was considered acceptable) for (GAD-7, PHQ-9, PSS-10)coGuide version V.1.0 was used for statistical analysis[15].

Results

The mean age was 52.39± 5.79 years in the study population. Proportion of males was 73 (50.34%) and 72 (49.66%) were female, majority of 135 (93.1%) was married. Majority as 71 (49.10%) were graduated and professionals, 37 (25.52%) did high school and 20 (13.79%) completed higher secondary. Hindu were 144 (99.31%) and 139 (95.86%) were living in urban area. Majority 106 (73.10%) were

from nuclear family. The mean duration of diabetes was 7.41± 6.39 (in year), majority 73 (50.3%) had diabetes >5 years in study population. As onset of disease, majority 108(74.5%) reported insidious. Diabetes diagnosed through Routine check-up for other illness in 84(57.9%) and in 40(27.6%) it was diagnosed while health screening. Majority of 114(78.6%) had obesity, 53(36.6%) had hypertension, 50(34.5%) had dyslipidaemia and 41(28.3%) had OA. Majority of 30(20.7%) had neuropathy followed by 3 (2.1%) had retinopathy and 1 (0.7%) had Neuropathy as micro vascular complications where Macro vascular Complication reported as 7 (4.8%) with CAD followed by 2 (1.4%) with PVD and 9 (6.2%) had ED as Other Complication. (Table 1)

Table 1: Baseline socio-demographic characteristics and clinical parameters of the study population (N=145)

Parameter	Variables	Summary
Age (mean±SD)		52.39± 5.79 (range 35 to 60)
Gender	**Male: female (ratio)**	73:72
Marital status	Single	4 (2.8%)
	Married	135 (93.1%)
	Widower/widow/divorced	6 (4.1%)
Education	Illiterate	4(2.76%)
	Middle school	13(8.97%)
	High school	37(25.52%)
	Higher secondary	20(13.79%)
	Graduate and professional	71 (49.10%)
Religion	Hindu	144(99.31%)
	Muslim	1(0.69%)
Locality	Urban	139(95.86%)
	Rural	6(4.14%)
Type of family	Nuclear	106(73.10%)
	Joint	39 (26.90%)
Duration of diabetes in years	**<1 year**	17 (11.70%)
	1 to 5 years	55 (37.9%)
	>5 year	73 (50.3%)
Mode of onset	Acute	14(9.7%)
	Sub-Acute	23(15.9%)
	Insidious	108(74.5%)
Co-Morbid conditions	Obesity	114(78.6%)
	Hypertension	53(36.6%)
	Dyslipidemia	50(34.5%)
	Hypothyroidism	22(15.2%)
	Cataract	11(7.6%)

Never smokers were 134 (92.4%), 8 (5.5%) were past smokers and 3 (2.1%) were current smokers. Alcohol habit was found only in 7(4.8%) participants. Majority 120 (82.8%) were doing sedentary work, followed by 21 (14.5%) working in light outdoor places, whereas 137 (94.5%) participants were vegetarian. (Table 2)

Table 2: Baseline lifestyle-related characteristics of the study population (N=145)

Lifestyle-relatedcharacteristics	Parameter	Summary
Smoking	Current	3(2.1%)
	Past	8(5.5%)
	Never	134(92.4%)
Alcoholic	Current	7(4.8%)
	Past	4(2.8%)
	Never	134(92.4%)
Type of work/ occupation	Sedentary	120(82.8%)
	Light outdoor	21(14.5%)
	Heavy outdoor	4(2.8%)
Dietary preference	Mixed vegetarian & non vegetarian	8(5.6%)
	Vegetarian	137(94.5%)

The Cohen perceived stress score was low in 27(18.62%), moderate in 101(69.66%) and high in 17(11.72%) participants. The GAD-7 anxiety score was mild in 55 (37.93%), moderate in 31 (21.38%) and high in 17(11.72%) participants. The PHQ score was mild in 42 (28.97%) and was severe in only 8(5.52%) participants. (Table 3)

Table 3: Summary of stress, anxiety and PHQ scores in the study population (N=145)

Baseline	Summary
Cohen perceived stress total score	18.77 ± 5.77 (ranged 1 to 33)
Low stress	27 (18.62%)
Moderate stress	101(69.66%)
High perceived stress	17 (11.72%)
Anxiety Severity	7.77 ± 4.91 (ranged 0 to 20)
Minimal anxiety	42(28.97%)
Mild anxiety	55 (37.93%)
Moderate anxiety	31 (21.38%)
Severe anxiety	17 (11.72%)
PHQ	8.34 ± 6.24 (ranged 0 to 27)

Normal	9 (6.21%)
Minimal depression	41 (28.28%)
Mild depression	42 (28.97%)
Moderate depression	27 (18.62%)
Moderately severe depression	18 (12.41%)
Severe depression	8 (5.52%)

The association of depression, stress and anxiety with different demographic parameters like Age, Education, locality, type of family and Duration of diabetes found to be insignificant with a *p* value (0.369, 0.478, 0.345,0.574, 0.515) respectively. Between gender there was statistically significant difference in severity of disease observed with a *p*-value of 0.006. (Table 4)

Table 4: Association of depression, stress and anxiety with demographic parameters (N=145)

Demographic parameters	Severe Disease		Chi square	P value
	Yes	No		
Age Group				
Up To 50 (N=45)	11 (24.44%)	34 (75.56%)	0.806	0.369
>50 (N=100)	18 (18%)	82 (82%)		
Gender				
Male (N=73)	21 (29.17%)	51 (70.83%)	7.511	0.006
Female (N=72)	8 (10.96%)	65 (89.04%)		
Education				
Illiterate (N=4)	2 (50%)	2 (50%)	3.498	0.478
Middle School (N=13)	3 (23.08%)	10 (76.92%)		
High School (N=37)	9 (24.32%)	28 (75.68%)		
Higher Secondary (N=20)	3 (15%)	17 (85%)		
Post-Graduate Or Professional Degree (N=71)	12 (16.9%)	59 (83.1%)		
Locality				
Rural (N=6)	2 (33.33%)	4 (66.67%)	0.695	0.345
Urban (N=139)	27 (19.42%)	112 (80.58%)		
Type Of Family				
Joint (N=39)	9 (23.08%)	30 (76.92%)	0.316	0.574
Nuclear (N=106)	20 (18.87%)	86 (81.13%)		
Duration of diabetes				
<1 Year (N=17)	2 (11.76%)	15 (88.24%)	1.327	0.515
1 To 5 Years (N=55)	10 (18.18%)	45 (81.82%)		
>5 Years (N=73)	17 (23.29%)	56 (76.71%)		

Discussion

The study aimed to assess the prevalence of depression, stress and anxiety among type 2 diabetics attending a community-based, peer-led lifestyle modification setting in India. The mean age was 52.39± 5.79 years in the study population with almost equal male and female ratio. The mean duration of diabetes was 7.41± 6.39 years. The Cohen perceived stress score was moderate among 101 (69.66%) participants. The GAD-7 anxiety score was moderate in 31 (21.38%) participants. The PHQ score was severe in only 8(5.52%) participants. The association of depression, stress and anxiety with different demographic parameters like Age, Education, locality, type of family and Duration of diabetes found to be insignificant with a P value (0.369, 0.478, 0.345,0.574, 0.515) respectively. Between gender there was statistically significant difference (p value of 0.006).Of 145 patients with type 2 diabetes mellitus, nearly 53(36%) of the patients exhibited moderate to severe depression and majority 118 (83%) showed perceived stress and nearly 48 (33%) had generalized anxiety disorders. This finding was very much similar to a cross-sectional study bySharma K et al[16] in Nepal where out of 296 patients with type 2 diabetes mellitus, more than half (57.8%) of the patients exhibited depression and nearly half (49.7%) showed generalized anxiety disorders. Regarding severity of depression, 42 (28.97%), 45(31%), 8(6%) patients had mild, moderate, and moderately severe, and severe depression, respectively. Although data related to severity from India are limited, a study in Saudi Arabia showed mild, moderate, severe, and extremely severe depression among 9.3%, 14.0%, 7.1%, and 3.3% of patients with type 2 DM, respectively[17]. Regarding severity of anxiety 55 (37.93%) , 31 (21.38%) and 11(17%) had mild, moderate and severe anxiety. Our finding is slightly higher than the finding reported by the study in India which showed overall prevalence of anxiety among 34% of patients where mild, moderate, and severe anxiety was found in 22%, 8%, and 4%, of patients, respectively, by GAD-7 scale [18]. In the present study 73 (50.3%) participants reported >5 years of duration of diabetes. This finding was similar to a cross-sectional study byGeleta BA et al [19] in southwest Ethiopia where the mean duration of stay with type 2 diabetes was 5.5 (SD = 3.9). Unlike the current study, the measurement tool used to measure depression was Beck Depression Inventory (BDI) scale questionnaire. Respondents aged 52.39± 5.79 (range 35 to 60) years 40–49 years more often showed emotional states of depression, stress and anxiety. This finding was similar to a cross-sectional study by [20] where logistic regression analysis indicated that age 40-49 years (OR=2.57, 95% CI: 1.59-4.13) as a predictor of depression and anxiety.Unlike the current study, the measurement tool used to measure depression, stress and anxiety was DASS-21. In the present study almost equal male and female ratio was observed 73:72. This finding was in contrast to a multicentric study by Ali Khan K et al [21] where there was a slight preponderance of females (57.5%) and Anxiety and depression was measured by using the Hospital Anxiety and Depression Scale (HADS). Various factors, such as age, education, locality, type of family and duration of diabetes were predicted to be associated with depression, stress and anxiety. But our study failed to prove this association. This finding was in contrast to a study by Camara A,[22] among African patients in Guinea, where variables such as gender, marital status, level of education, DM duration, smoking status, number of doctor's visits, DM therapy, and comorbidities, were predicted to be associated with depression, stress and anxiety. In the current study high perceived stress was observed in 17 (11.72%) participants. This finding can be compared to a subset analysis of the nationwide cross-sectional survey, conducted across Indian zones under the National Multicentric Diabetes Control Program by Mishra A et al [23] where people with prediabetes were under more stress as compared to those with diabetes in India. The life style modification

program to reduce the levels of HbA1c and to reduce the burden of depression, stress and anxiety was very much similar to Kerala diabetes prevention program (K-DPP) [24] where the context was interlinked with evidence-based behaviour change techniques that benefited policy makers, action implementers, service providers, and eventually wider populations in India and similar countries.The lessons learnt from the implementation of such interventions would also have applicability to other rapidly developing low- and middle-income countries in the Asia, Pacific and African regions where there is an urgent need of such interventions to control psychological burden of diabetics.

Strength

This study adds to the limited information available regarding anxiety and depression and stress among type 2 diabetics attending a community centre for life style modification in India. According to authors knowledge, this was the first study to examine co- occurrence of depression, anxiety and stress among type 2 diabetics attending a life style modification centre in India using three different scales.

Limitations

It is descriptive cross-sectional study which could not explore the causal relationship between anxiety, stress and depression with other associated factors. The study was conducted at a life style modification centre and only type 2 diabetic patients were considered which did not allow for generalizability of the findings to the entire diabetics. The study sample was also low that can affect the study findings. The study was based on participants response to questionnaire and hence can be subjected to recall bias. Considering these limitations, further multicentric interventional population-based studies are recommended to support the findings of the present study.

Conclusion

Depression, stress and anxiety was high among type 2 diabetics. An integrated model to manage symptoms of depression, stress and anxiety is to be developed focusing on early screening and counselling by psychiatrists. While planning and implementing the program for this risk groups in the healthcare settings, early screening and counselling can enhance the efficacy of treatment regimens and reduce overall burden and improve quality of life of diabetics.

Dear Authors

We are pleased to inform you that your Original Research Article (Title: **Role of Nasal Douching in Chronic Allergic Rhinitis**) has been accepted for publication in **Tropical Journal of Ophthalmology and Otolaryngology**.

We are planning to finalize and publish your article in the issue of April June of our **Tropical Journal of Ophthalmology and Otolaryngology**. We may ask you for any minor corrections if we found anything at drafting and finalizing the article.

We shall send Galley proof of article before publication. Kindly see the attachments for further processing.

Your accepted article no is: TJOO 2019-12

Date: 18th May 2019

ABSTRACT

BACKGROUND: Vertigo is a very common medical condition with a broad spectrum of diagnoses and requires an integrated approach to patients through a structured clinical interview and physical examination. The main cause of peripheral vertigo in primary care is benign paroxysmal positional vertigo (BPPV), which should be confirmed by a positive Dix-Hallpike positional test and treated with repositioning maneuvers. The objective of this study is to compare the effectiveness of Epley's maneuver alone or Epley's maneuver with medications in the treatment of BPPV. **MATERIALS AND METHODS:** the study was a randomized clinical trial conducted in the department of otorhinolaryngology at pacific Medical college & Hospital, Udaipur from January, 2014 to January, 2015. A total of 70 patients of BPPV confirmed by Dix-Hallpike test were included in the study out of which 35 patients were treated by Epley's maneuver alone and rest 35 were treated by Epley's maneuver along with medications. **RESULTS:** Total 70 patients were included in our study out of which 35 patients who received medications along with Epley's therapy were considered as cases and rest 35 patients who received only Epley's therapy were considered as controls. The mean age of cases was 55.23, that of the control group was 53.74. 15 patients (42.85%) among cases were having associated nausea and vomiting while 12 patients (34.28%) in the control group were having associated nausea and vomiting. 1 day after treatment, 27 patients (77.14%) among the cases and 26 patients among controls were free of positional vertigo (p-value=0.001). similarly, after follow up of 1 week, 1 month and 6 month duration, the number of patients relieved after respective treatment were similar in both cases and control. **CONCLUSION:** Epley's maneuver alone is safe and effective method to treat BPPV. However, medical treatment can be used to treat associated symptoms like nausea and vomiting.

Keywords: BPPV, Betahistine, Dix-Hallpike maneuver, Epley's maneuver, Vertigo

INTRODUCTION

Vertigo is the feeling that you or your environment is moving or spinning. It differs from dizziness in that vertigo describes an illusion of movement. When you feel as if you yourself are moving, it's called subjective vertigo, and the perception that your surroundings are moving is called objective vertigo. Vertigo can be caused by problems in the brain or central nervous system (central vertigo) or the inner ear (peripheral vertigo).

The most common cause of vertigo is a peripheral vestibular dysfunction called benign paroxysmal positional vertigo[1]. This is an acute condition that always presents with a combination of positional vertigo and Nystagmus[1,2]. The diagnosis of BPPV is based on both subjective symptoms and objective signs. A provoking maneuver called the Dix-Hallpike test is used on patients who are complaining of vertigo symptoms and are suspected of having BPPV. It is performed by keeping the individual's head in slight extension and 45 degrees of rotation to the test side. The individual is then moved by the tester from sitting to supine. If there is an up-beating, rotatory nystagmus toward the ear that is lower, then the test is considered positive. A positive Dix-Hallpike test and complaints of vertigo symptoms are considered the gold standard for diagnosing BPPV[3].

It is theorized that BPPV is due to either canalithiasis or cupulolithiasis[1]. Both etiologies are explained by displacement of the otoconia from the macula due to trauma, infection, or unknown cause[2]. Canalithiasis occurs when the displaced particles are floating in one or more

Assistant professor, Department of ENT,
5, Meera Nagar, behind Sky Height Apartment,
Shobhagpura, Udaipur

the endolymph[1]. The cupula is then bent by this flow and sends an incorrect signal to the brain regarding the body's movement in relation to gravity[3]. Cupulolithiasis, on the other hand, occurs when the displaced particles stick to the cupula itself. Ultimately, this produces the same effect that canalithiasis does because is produces an abnormal bending of the cupula and an incorrect signal to the brain[1]. Regardless of the theorized mechanism, both conditions result in vertigo. Currently, the standard treatment for BPPV is the canalith repositioning procedure[4]. The physical therapy maneuver we usually use is called the Epley's maneuver. First, while sitting up, the patients head is turned about 45 degrees to the side that normally provokes the vertigo. Then the patient is quickly laid down backwards with their head just over the edge of the examining table. This position usually provokes strong vertigo. The head is kept in this position for about 30 seconds and then turned 90 degrees to the opposite side. After another 30 seconds, the head and the body are turned together in the same direction so that the body is pointing towards the side, and the head is pointing down toward the ground at a 45 degree angle. After 30 seconds in this position, the patient is brought upright again. This is repeated as many as five or six times until neither vertigo nor nystagmus are elicited when the head is brought into the bad ear down position. Usually no medications are required for BPPV unless the patient has severe nausea or vomiting. If extreme nausea does exist, anti-nausea medications can be prescribed before and/or after the treatment. In present study, we compared the effectiveness of using Epley's Maneuver alone or Epley's maneuver with medications like labyrinthine sedative (i.e. beta-histine) in the treatment of BPPV.

MATERIALS AND METHODS

This study was a randomized clinical trial and was conducted among patients attending the Department of Otorhinolaryngology at Pacific Medical College and Hospital, Udaipur during the period from January 2015 to January 2016 and at Ananta Institute of Medical sciences, Rajsamand during the period from Febrary 2016 to September 2016. A total of 70 patients of BPPV were included in the study. The clinical diagnosis of BPPV was confirmed by Dix-Hallpike maneuver. **Exclusions:** The patients [illegible] BPPV [illegible] ongoing CNS disease (stroke or TIA), and cardiovascular disease and pregnant women beyond 24 weeks were excluded from this study. All the 70 patients with positive Dix-Hallpike test were divided in two groups each consisting of 35 patients. One group of 35 patients who received medical therapy with Epley's maneuver were considered as the cases and the other group of 25 patients who received only Epley's maneuver were considered as the controls. Epley's maneuver was repeated until symptomatic relief. We used labyrinthine sedative drug beta-histine 16mg tds in all the 35 cases. We followed the patients for one year with review visit after 1 week, 1 month and 6 months. The results were assessed on following criteria:

1. Negativization of the D-H test at a week, a month and six month follow-up
2. Answer to the dichotomous (yes/no) question regarding presence of vertigo in the previous week.
3. Number of new episodes of vertigo between medical visits.
4. Time from the baseline visit to the first new episode.

Those who meet the following three criteria: presenting no exclusion criteria, all inclusion criteria met, and signed informed consent, were randomized to the intervention group or the control group. The responsibility for guarding and supervising the randomization list was rest on a staff member of center who was not directly involved in the trial.

RESULTS

Total 70 patients were included in our study out of which 35 patients who received medications along with Epley's therapy were considered as cases and rest 35 patients who received only Epley's therapy were considered as controls. The mean age of cases was 55.23 that of the control group were 53.74. There was no statistically significant difference between the age groups (p-value=0.5093). In the study group 45.71% were male and 54.29 % were female while in the control group, 37.145 were male and 62.86% were female. Sex ratio difference between two groups was not statistically significant (p-value=0.6275). 57.15% of cases were having left sided BPPV and remaining 42.85% were having right sided BPPV. [illegible]

having left sided disease and 31.43% were having right sided BPPV. There was no statistically significant difference was found in terms of affected sides. Patients diagnosed with bilateral BPPV were excluded from the study. 15 patients (42.85%) among cases were having associated nausea and vomiting while 12 patients (34.28%) in the control group were having associated nausea and vomiting. Treatment response was detected by negative Dix-Hallpike test at the follow up after 1 day, 1 week, 1 month and at 6 month. 1 day after treatment 27 patients (77.14%) among the cases and 26 patients among controls were free of positional vertigo. similarly, after follow up of 1 week, 1 month and 6 month duration, the numbers of patients relieved after respective treatment were similar in both cases and controls (p-value=0.99) 2 patients among cases developed recurrence at 4th and 6 month respectively while 1 patient in controls developed recurrence in 4th month and they were treated in similar manner.

Table 1: Dose response relationship between cases and controls among BPPV patients

	1 Day No(%)	1 week No(%)	1 Month No(%)	6 Month No(%)	Recurrence No(%)
Cases	27 (77.14)	32 (91.42)	35 (100)	35 (100)	2 (5.71)
Controls	26 (74.28)	32 (91.42)	34 (97.14)	35 (100)	1 (2.85)

Table 2: Number of patients with associated symptoms (nausea, vomiting) relieved after respective treatment

	1st day	1 week	1 month
Cases (n=12)	7 (58.33%)	11 (91.66%)	12 (100%)
Controls (n=15)	5 (33.33%)	12 (80%)	15 (100%)

After 1 day of treatment, 7 patients (58.33%) among 12 patients with nausea and vomiting in cases were recovered completely from symptoms while only 5 cases(33.33%) among 15 patients from control group with nausea and vomiting treated completely (p-value < 0.001). after 1 week follow up, 91.66% of suffered cases and 80% of controls were treated completely. At 1 month follow up, all the cases and controls were free of associated symptoms.

DISCUSSION

Schuknecht developed the cupulolithiasis theory in studies concerning pathogenesis of this disorder in 1963[5]. However, later on, Epley claimed that BPPV was a result of canalolithiasis him[6]. Several other authors developed techniques and therapy protocols to be used in treatment of BPPV. For example Semont describes Semont maneuver[7], Cawthern developed 'rehabilitation therapy'[8], Brandt and Daroff described home exercise programs named after their names[9]. The relevance of medical treatment in BPPV is controversial. Betahistine dihydrochloride, which has a mechanism of action based on interaction with H1 and H2 receptors, is being used in the treatment of vertigo. This molecule acts through inhibition of activation in vestibular nuclei, diminishing the resting flow of ampullary hair cells in the labyrinth and increasing cochlear blood flow[10]. Hence, various studies are focused on this matter. Cavaliere compared the Liberatory and Brandt-Daroff procedures on their own and with Betahistin and in the short term, he achieved a higher success in the Betahistin group. However, achievement of complete cure in all the groups at the end of three months suggests that BPPV recovers spontaneously[11]. However, there is controversy on whether the consideration of subjective criteria obtained from patients as an indication for success in this study is beneficial, especially for the basic mechanism of the disease or for the imbalance period that follows. In the present study, we found that up to 91.42% of patients reported benefit after the first follow-up period of one week. In a randomised study, 90% of patients were either improved or cured after a single session with either Semont's or Epley maneuver [12]. Epley himself reported a success rate of more than 90% following a single treatment session. Among 35 case patients, 27 (77.14%) recovered from vertigo immediately after the Epley maneuver and 32 (91.42%) patients recovered from vertigo at first week of follow up. The remaining 3 case patients recovered from vertigo during second and third follow-up visits, whereas, among 35 control patients, 26 (74.28%) recovered from vertigo immediately after one day 32 (91.42%) participants recovered from the vertigo at first follow up after one week.. This clearly indicates that Epley's maneuver alone is sufficient for the treatment of BPPV and addition of medical therapy does not improve or affect the response. In our study labyrinthine sedatives beta-histine 16 mg thrice a day was given to all 35 cases

the patient is symptom free. Labyrinthine sedatives did not change the effectiveness of Epley's maneuver in treating BPPV even after prolonged use, although they may provide minimal relief in associated symptom like nausea and vomiting in some patients. A review of the literature revealed the extremely good results of the Epley maneuver. In one study, the success rate after1week was 63.6%, which increased to72.7% after 2 weeks[13]. One Brazilian study also revealed similar results [14]. A meta-analysis done by Prim-Espada et al. on the efficacy of Epley's maneuver in benign paroxysmal positional vertigo using a critical review of the medical literature concluded that the patients on whom Epley'smaneuver was performed had six and half times more chance of their clinical symptoms improving compared to the control group of patients (OR = 6.52, 95% CI, 4.17–10.20)[15]. The efficacy of Epley's maneuver in the treatment of BPPV was assessed in a study of 62 patients conducted by Khatri et al. Patients were selected based on symptoms of positional vertigo and positive Dix-Hallpike's test. At the end of 1 month patients were assessed subjectively by visual analogue scale (VAS) and objectively by Dix-Hallpike's positional test. On VAS, 85.7% of patients had complete resolution of symptoms of BPPV in both groups. Objectively 88.2% did not have positional nystagmus after 1 month in first group, whereas in the second group 86% had complete response at the end of 1 month of therapy[16]. In a prospective study liberatory maneuver-betahistine and Brandt-Daroff-betahistine groups did significantly better than liberatory maneuver and Brandt and Daroff groups ($p < 0.05$). This study signifies the added efficiency of betahistine with particle repositioning maneuver in treating BPPV [17]. However there are very few studies which have compared the medical therapy with the particle repositioning maneuver. In present study, addition of beta-histine did not change the efficacy of Epley's maneuver in treating BPPV, but relief in associated symptoms like nausea and vomiting was more in cases where we used beta-histine than controls that were treated with Epley's maneuver alone.

CONCLUSION

BPPV is a very common disease in society and Neuroclinics. The symptoms of BPPV are very distressing for the patient and can deteriorate the quality of life of the patient. Luckily, it is an easily diagnosed and treated cause of vertigo. In present study, we have investigated whether a change in treatment success occurs when Epley's maneuver is combined with medications. There was no significant difference among the groups. Applying only the Epley's maneuver to the patients we diagnosed to be with BPPV seems to have been sufficient for achieving a cure. However, in case of associated symptoms like nausea and vomiting that can occur during the treatment and dizziness that can continue after the treatment, medical treatment can be of use.

ABSTRACT

Background: Tympanoplasty, also called eardrum repair, refers to surgery performed to reconstruct a perforated tympanic membrane (eardrum) or the small bones of the middle ear. Eardrum perforation may result from chronic infection or, less commonly, from trauma to the eardrum.

Objective: The Objective of the study is to evaluate the surgical outcomes of tympanoplasties with and without mastoidectomies in terms of graft uptake and hearing improvement.

Methods: A total of 56 patients undergoing tympanoplasties with and without mastoidectomy were included and followed up for a period of one year.

Results: There was no significant difference in the surgical outcomes of both the surgeries in terms of graft uptake and hearing improvement. In unilateral cases Belfast rule of thumb application enables the actual hearing benefit of the patient.

Conclusion: There is no difference in related to outcome. The addition of cortical mastoidectomy to tympanoplasty did not improve the outcome of surgeries done for mucosal type of chronic suppurative otitis media.

KEY WORDS: Cortical Mastoidectomy, Tympanoplasty, Belfast Rule.

INTRODUCTION

Tympanoplasty, also called eardrum repair, refers to surgery performed to reconstruct a perforated tympanic membrane (eardrum) or the small bones of the middle ear. Eardrum perforation may result from chronic infection or, less commonly, from trauma to the eardrum.

The tympanic membrane of the ear is a three-layer structure. The outer and inner layers consist of epithelium cells. Perforations occur as a result of defects in the middle layer, which contains elastic collagen fibers. Small perforations usually heal spontaneously. However, if the defect is relatively large, or if there is a poor blood supply or an infection during the healing process, spontaneous repair may be hindered. Eardrums may also be perforated as a result of trauma, such as an object in the ear, a slap on the ear, or an explosion [1]. The purpose of tympanoplasty is to repair the perforated eardrum, and sometimes the middle ear bones that consist of the incus, malleus, and stapes. Tympanic membrane grafting may be required. If needed, grafts are usually taken from a vein

or fascia (muscle sheath) tissue on the lobe of the ear [2]. Synthetic materials may be used if patients have had previous surgeries and have limited graft availability. The mastoid is a honeycomb cavity in the temporal bone, which lies directly behind the ear and is connected to the middle ear space. When a hole arises in the eardrum due to previous injury or infection, or when a long-standing infection persists with tissue in the middle ear or mastoid, mastoid surgery often becomes necessary to alleviate this infection. This part of the procedure is called mastoidectomy. Surgery for tubotympanic type of chronic suppurative otitis media is the commonest otological surgical procedure in our country [3].

This study discusses the various pre-operative factors which play a major role in the post-operative success of two various surgeries – myringoplasty and cortical mastoidectomy with type 1 tympanoplasty. The hearing benefit is determined by Air bone gap closure and also subjective evaluation of hearing is done by applying Belfast rule of thumb.

MATERIALS AND METHODS

This Prospective study was conducted at RNT medical college and attached M.B hospital, Udaipur, Rajasthan from Dec 2009 to Dec 2011. Study involves total 56 patients attending ENT OPD with mucosal disease at Our hospital for a period of one year and the patients were followed up for a period of one year. Among them, 6 patients did not turn up for follow up and they were excluded from the study.

Inclusion criteria: Patients between 15 to 50 years of both sexes, after elimination of focal sepsis, having either wet or dry ears and pure tone audiometry showing conductive hearing loss.

Exclusion Criteria: Patients with congenital or acquired abnormalities of ear, unsafe ear, undergone ear surgeries previously and with pure tone audiometry showing mixed and sensorineural hearing loss were excluded from the study.

Methodology: Minimum duration of discharge for the patients under study was 1year and maximum was 15 years. Minimum duration of hearing impairment was 6 months and maximum was 10 years. For all patients, under study with wet ears, ear swabs were taken from middle ear and for patients with culture positive results, treated with specific antibiotics prior to surgery.

All cases were admitted, pre-operative examination done under microscopy, subjected to endoscopic eustachian tube evaluation (those with normally looking pharyngeal end of eustachian tube orifice were taken up for study) and hearing assessment done with tuning fork tests and pure tone audiogram. All patients were informed about their need for a follow up period of one year. Informed written consent to undergo surgery was obtained from all patients. Mastoid shaving and local preparation was done in the ward prior to surgery. All cases were done under GA. Premedication and local infiltration was same for all cases.

Group A: About 25 patients with dry ear for more than 6 weeks and with only conductive hearing loss, were subjected to myringoplasty and considered as Group A. About 13 patients with unilateral disease and 12 patients with bilateral disease were taken up for study. For patients with bilateral disease, worse ear was taken up for surgery. All patients were taken up for surgery under GA. Trans canal approach was followed in 21 cases and in 4 cases with narrow external auditory canal post- aural approach was followed. 4 quadrant local infiltration was given with 2% xylocaine with adrenaline premixed solution. Temporalis fascia graft harvested by a separate incision over supra auricular region for patients done through trans-canal approach & in patients done through post-aural approach, graft was harvested via the same incision. Temporalis fascia graft kept by underlay technique. All cases were followed up for 3,6 months and one year for graft uptake and postoperative hearing evaluations done at 3,6 months and one year. Results of hearing benefit, compared with pre-op and post-op air bone gap and for unilateral disease Belfast rule of thumb applied.

Group B: About 25 patients with wet ear and with no active infection as per microbiological report & with conductive hearing loss were subjected to cortical mastoidectomy with type 1

tympanoplasty and considered as Group B. About 15 patients with unilateral disease and 10 patients with bilateral disease were taken up for study. For patients with bilateral disease, worse ear was taken up for surgery.

All patients were taken up for surgery under GA. Post-aural approach was followed in all cases. Postaural incision made, temporalis fascia graft harvested through the superior aspect of the incision as the first step, incision deepened and mastoid cortex exposed. Pinna retracted anteriorly, incision made in the posterior canal wall skin from 6 o'clock to 12 o'clock position and tympanomeatal flap was elevated. Granulations if present in the tympanum were removed, mobility of ossicular chain were checked. Mastoid cortex was drilled out in all cases, patency established. For about 21 patients granulations noted in antrum removed and in 4 patients antrum found free of disease. For all patients, temporalis fascia graft kept by underlay technique, tympanomeatal flap repositioned and post-aural wound closed in layers. All cases were followed up for 2, 6 months and 1 year for graft uptake and post-operative hearing evaluations done at 3, 6 months and 1 year. Results of hearing benefit, compared with pre-op and post-op air bone gap and for unilateral disease, Belfast rule of thumb applied.

Even though socio-economic status does influence the disease, all the patients attending RNT Medical College and M B Hospital Hospital belongs to lower socio-economic group. Hence this parameter is not included in this study.

RESULTS

Total number of cases registered in this study was 56 patients, who came to the ENT Department with Mucosal disease. Among them 6 patients did not turn up for follow up and hence they were not included in the study.

The overall graft take up rate in both the surgeries was 88.33%. The overall hearing benefit was 90%, excellent with < 10dB ABG in 51.67% and Good with < 20dB in 38.33%. There was no postoperative complications, deterioration in hearing or sensorineural hearing loss in all 50 patients.

In Group A ,15 were females & 10 were males, 13 patients had unilateral and 12 had bilateral disease, 20 had medium sized central perforation and 05 had subtotal perforation, 10 had good pre-op Air bone gap of 10 to 20 dBHL 15 patients had a fair pre-op Air bone gap of 20 to 30 dBHL.

1. Overall graft take up rate was 86.6%.

2. Otoscopic evaluation of 20 patients with medium sized perforation at the end of 2 months, revealed 15 to be intact, 5 residual perforation in the antero - inferior quadrant. In 5 patients with subtotal perforation,3 were intact,1 with residual perforation & 1 grafts got rejected because of post-op wound infection. Otoscopic examination at the end of 6months & 1 year revealed – for all 20 patients with medium size perforation, tympanic membrane was intact and out of 5 patients with subtotal 2 were with residual perforation & 1 with rejection of graft. Hence the size of the perforation does have a role in graft take up rate. This is statistically significant by applying chi square test with p value < 0.05.

3. In 10 patients with good pre-op ABG, the post-op ABG was excellent. In 15 patients with fair pre-op ABG, the post-op ABG results were, excellent in 9, good in 8 and fair in 3 patients accounting for 46.66% in excellent, 40% in good and 13% in fair groups. By applying Chi square test, these results are statistically significant Hence, for the patients with lesser pre-operative Air bone gap have a better post-operative hearing.

4. When Belfast rule of thumb was applied to 13 patients with unilateral disease, 10 of them with medium sized perforation, felt subjectively better and out of 3 of them with subtotal perforation, 2 felt better &1 patient felt hearing same as the pre operative status. These results are statistically significant with p value<0.05, implies that Belfast rule of thumb interpret the post-operative hearing benefit in a better way than the Air bone gap ,which tells about only the technical success.

5. The correlation coefficient between the duration of discharge and the pre-op ABG is 0.4172 and that between the duration of hearing impairment with pre-op ABG is 0.3821 and is statistically significant. The correlation coeffici-

-ent between the duration of discharge and the post-op ABG is 0.4544 and that between the duration of hearing impairment with post-op ABG is 0.4489 and is statistically significant, implies that the patients with lesser duration of discharge and hearing impairment had better post operative hearing than the patients with longer duration of disease and hearing impairment.

6. The other parameters, such as age, sex, weight does not have influence on the outcome of results in this study.

7. The type of approach does not have a significant p value with graft intake in this study. Applying chi square test, the Pearson value is 0.

In Group B, 17 were females & 8 were males, 15 patients had unilateral and 10 had bilateral disease. 18 had medium central perforation and 07 had subtotal perforation. 08 had good pre-op Air bone gap of 10 to 20 dBHL 17 patients had a fair pre-op Air bone gap of 20 to 30 dBHL.

1. Overall graft take up rate was 90%.

2. The relationship between Graft take up rate and size of the perforation is statistically significant by applying chi square test with person value of 0.02535.

Otoscopic evaluation of 15 patients with medium sized perforation at the end of 2 months, revealed 14 to be intact, 1 residual perfpration in the antero-inferior quadrant. In 07 patients with subtotal perforation, 05 were intact, 2 with residual perforation. Otoscopic examination at the end of 6 months & 1 year revealed – for all 18 patients with medium size perforation, tympanic membrane was intact and out of 07 patients with subtotal 3 were with residual perforation. Hence the size of the perforation do have a role in graft take up rate even when cortical mastoidectomy is done along with repair of tympanic membrane.

3. In this study, out of 18 patients with medium sized perforation, 8 had a good & 17 had fair pre-op ABG. Out of 07 patients with subtotal perforation, 6 patient had good & 01 had fair pre-op ABG, implies that 85.71 %of the patients with subtotal perforation had pre-op ABG of 20 to 30 dB.

4. Out of 25 patients, included in this procedure -re, 50% had excellent, 50% had good &10% had fair post-op ABG. Those with medium sized perforation had better results than those with subtotal perforation.

5. On comparison of pre-op ABG & post-op ABG, all 8 patients with good pre-op ABG improved to excellent, out of 17 with fair ABG, 3 were excellent, 12 were good and 2 were fair post-operatively. This result is highly statistically significant with pearson value of 0.00006 .

6. Graft intake in 4 patients with disease free antrum mucosa is 100%.

7. Out of 25 patients, 21 patients had disease in the antrum & 4 had a healthy antrum. 77.85% of the patients with healthy antrum and 9.5% of the patients with diseased antrum had good pre-op Air bone gap 90.5% with diseased and 22.2% with healthy antrum had fair preop Air bone gap.

8. In patients with healthy antrum, the post-op ABG was excellent in 88.9% and 66.7% of the patients

with diseased antrum had a good ABG post-operatively.

9. On applying Belfast rule of thumb to 15 patients with unilateral disease, 83.3% had better hearing, implies the post-operative hearing benefit better than assessment with Air bone gap.

10. The correlation coefficient between the duration of discharge and the pre-op ABG is 0.3803 and that between the duration of hearing impairment with pre-op ABG is 0.3776. The correlation coefficient between the duration of discharge and the post-op ABG is 0.3794 and that between the duration of hearing impairment with pre-op ABG is 0.3729 and are statistically significant, implies that the patients with lesser duration of discharge and hearing impairment had better post-operative hearing than the patients with longer duration of disease and hearing impairment.

11. The other parameters, such as age, sex, weight does not have influence on the outcome of results in this study.

DISCUSSION

Analysis of 50 cases undergone surgery for tubotympanic disease is presented here and the

same is compared with similar and related studies available in literature.

1. Graft Take Up Rate: The overall graft take up rate in Myringoplasty in this study was 86.6%, which is within the range to the studies available. The graft take up rate in various studies were [Table 1].

Table 1: Graft take up rate [1]

Study	No of cases	year	Graft take up rate
Gibb, Chang et al [5]	365	1982	91.40%
Black, PJ Wormald [3]	261	1995	78%
Raj A Vidit [1]	50	1999	84%
Kotecha et al [7]	107	1999	82.20%
Yasuo, Mishiro et al [1]	104	2001	94.40%
Kageyama et al [6]	290	2001	82.10%
Alberra et al [2]	85	2006	86%

The graft take up rate in Cortical mastoidectomy with type 1 tympanoplasty is 90% which is also within the range to the studies available in literature [Table 2].

Table 2: Graft take up rate [2].

Studies	No of cases	Graft take up rate
Yasuo, Mishiro et al [1]	147	90%
Adnan saleem et al [2]	85	92.95%
McGrew et al [2]	100	791%
Rehl CM et al [2]	135	90.40%

2. Graft Failure Rate: Graft failure rate in various studies were [Table 3].

Table 3: Re-perforation Rate % [1].

Studies	Re-perforation Rate %
Alberra et al [2]	7 to 21
Vartiainen et al [14]	10.6
Adnan, saleem et al [2]	7.05

In this study, in myringoplasty series the rate of residual perforation is 6.7% and the rate of rejection of graft is 6.7%. The probable cause of residual perforation is the slippage of the graft from its position and the cause for rejection is the post operative infection of the operated site, which is same as the reason cited by the study of Vartianien et al and Kotecha et al.[7,14] Study of Alberra et al also includes the efficiency of the surgeon and the surgical techniques [2].

3. Pre-operative Hearing: In this study the pre operative pure tone average in Myringoplasty series was between 30 to 40 dB with average being 38 dB and in Cortical mastoidectomy with type 1 tympanoplasty series between 30 to 55 dB with average being 42.16 dB. As the perforation size increases, the preoperative hearing threshold also increases – this is consistent with the study conducted by Mehta et al, Bhusal et al Nepal A Bhandary et al, Kageyama etal, Alberra et al and Saeed et al.[1,2]

4. Post Operative Hearing Benefit: Hearing improvement in various studies quoted in literature were [Table 4];

Table 4: Hearing improvement [2,3].

Study	Hearing Improvement
Adnan et al [2]	85.88%
Riser et al [2,3]	84.90%
Raj A Vidit et al [2]	68%
Kotecha et al [7]	67%

In this study, the overall post operative hearing benefit based on Air bone gap was 90% with <10 Db in 51.67% and <20db in 38.33%. As hearing benefit is better assessed with the subjective evaluation, in this study we have applied Belfast rule of thumb in patients with unilateral disease. In 23 patients with unilateral disease in Myringoplasty series, 95.7% felt significant improvement in hearing and 4.3% felt no improvement. In 18 patients with unilateral disease in Mastoidectomy with type 1 tympanoplasty series, 83.3% felt significant improvement in hearing and 16.7% felt no improvement.

CONCLUSION

From Our study we Would like to conclude that the success of Myringoplasty in terms of graft uptake and hearing improvement is better in patients with lesser duration of disease, less preoperative Air bone gap and with medium sized perforations when compared to subtotal perforations. The success of Cortical mastoidectomy with type tympanoplasty in terms of graft uptake and hearing improvement is better in patients with lesser duration of disease and less pre-operative Air bone gap.

Dear Authors, Rajiv Kumar Saxena, Hemendra Bamaniya (Corresponding author), H.S. Bhuie

We are pleased to inform you that your Original Research Article (Title: Role of Nasal Douching in Chronic Allergic Rhinitis) has been accepted for publication in Tropical Journal of Ophthalmology and Otolaryngology.

We are planning to finalize and publish your article in the issue of April June 2019 (in Volume- 4, Issue 2 of 2019 will be published in next 2-3 weeks) of our Tropical Journal of Ophthalmology and Otolaryngology. We may ask you for any minor corrections if we found anything at drafting and finalizing the article.

We shall send Galley proof of article before publication. Kindly see the attachments for further processing.

Your accepted article no is: TJOO 2019-12

Date: 18th May 2019

ORIGINAL ARTICLE

Comparison between Voice Handicap Index and Voice Symptom Scale by Subjective Analysis of Voice Disorders

[1]Hemendra Samariya, [2]Alok K Vaishnav, [3]Shashank Joshi, [4]Harbinder S Bhuie, [5]Rajiv K Saxena

ABSTRACT

Objective: Purpose of the present study was to use and compare two patient-derived scales voice handicap index (VHI) and voice symptom scale (VoiSS) for the assessment of the quality of life in patients of voice disorders and to assess their response to treatment.

Design: Longitudinal, cohort comparison study.

Setting: Department of Otorhinolaryngology, Maharana Bhupal Government Hospital, Udaipur, Rajasthan.

Participants: Fifty patients with a complaint of change in voice attended ear, nose and throat outpatient department at Maharana Bhupal Government Hospital and Rabindranath Tagore Medical College, Udaipur from 7th July 2010 to 30th June 2011.

Materials and methods: Two self-reported patients derived scale VHI and VoiSS were applied to all 50 patients of voice disorders both before as well as after treatment and compared the effect sizes of both the scales.

Result: Out of 50 cases, predominant cases included in the study were of malignant growth larynx (30%) followed by vocal nodule (18%). A total of 60% were male, and 40% were female. Maximum cases were of 41 to 60 years of age group (48%). Both the patient-derived scales VHI and VoiSS were found equally useful in assessing the quality of life in patients of voice disorders. Outcomes were similar in both the scales. The mean scores in both the scales before treatment were reduced to almost half after the respective treatment.

Conclusion: The result suggested that both the scales (VHI and VoiSS) are equally important as the results were highly correlated and no strong evidence was found to favor either of the scales. These scales are very useful in the assessment of the impact of voice disorders on patient's life and improvement in the quality of life after respective treatment as well as in assessing response to treatment.

Keywords: Dysphonia, Quality of life, Voice handicap index (VHI), Voice disorders, Voice symptom scale (VoiSS).

INTRODUCTION

Voice is a complex phenomenon that is produced by interaction among the respiratory, laryngeal and resonance sub-systems.[1]

The phonation or voice is produced when the air is expelled from the lungs through the glottis, creating a pressure drop across the larynx. The oscillations of vocal cords modulate the pressure and flow of the air through the larynx, and this modulated airflow is the main component of the sound of most voiced phones.

Describing the vocal function and evaluating the voice problems are, likewise, complex tasks.

Voice measurement can improve our understanding of voice production, helps us to identify links between laryngeal disorders and voice production, and document change with interventions. It is also an important part of all phonatory surgery.[2]

Voice measures are divided into three categories:

1. Patient scales
2. Perceptual evaluation
3. Measures

Patient Scales

- VHI
- VoiSS
- Voice Related Quality of Life (V-RQOL)
- Voice activity and participation profile (VAPP)
- Reflux symptom scale (RSI)
- Patient questionnaire of vocal performance (VPQ)
- Voice outcome survey (VOS)

Perceptual Evaluation

- Auditory perceptual scale
  - Grade, roughness, breathiness, asthenia, and strain (GRBAS)

b. Consensus auditory perceptual evaluation-voice (CAPE-V),
c. Vocal profile analysis (VPA)
- Visual perceptual scale
- Tactile perceptual evaluation

Measures

Measuring voice is accomplished using:
- Acoustic analysis,
- Aerodynamic assessment, and
- Source measures.

Dysphonia can be defined as an impairment of the speaking or singing voice. It arises from an abnormality of the structures and or functions of the voice production system and can cause bodily pain, personal communication disability or an occupational or social handicap. The etiology of dysphonia is multifactorial. Genetic and psychological factors may predispose an individual to voice disorders.[2]

There are so many acute and chronic variables which can precipitate dysphonia. These include occupational vocal demands, trauma, environment, medications, health problems and lifestyle choices. Dysphonia is as disruptive to quality of life as any other chronic disease like angina, sciatica and chronic sinusitis.[3] The communicative issues associated to dysphonia can lead to depression, social withdrawal, and occupational handicap.[4]

OBJECTIVE

The objective of the present study is to use and compare VHI and VoiSS for the assessment of the quality of life in patients with voice disorders and their response to treatment.

Voice Handicap Index

It is a voice-specific outcome, measures patients' disability from voice disorders.

The index consists of a 30-item questionnaire, and each statement is noted from 0 (never) to 4 (always) composing a total score from 0 to 120, the higher the standard score, the higher the VHI (Table 1).

Voice Symptom Scale

This scale is yet in progress.

VoiSS consists of 43 items on a five-point equal appearing interval scale that reflects the frequency of occurrence. The total score is 0 to 172 (Table 2).

The questions in VoiSS represent five aspects (or domains) of voice pathology-communication problems, throat infection, psychosocial distress, voice sound, and variability and phlegm.

MATERIALS AND METHODS

This study was carried out on 50 patients that came to Otorhinolaryngology OPD at Maharana Bhopal (M.B.) Hospital and R.N.T. Medical College, Udaipur from 7th July 2010 to 30th June 2011 with a clinical diagnosis of dysphonia.

All patients then underwent thorough history-taking, general physical examination, and uniformly documented detailed local examination.

The routine laboratory tests, viz. blood for Hb, TLC, DLC, ESR, urinalysis, sklagram soft-tissue neck lateral view, sklagram chest PA view were done in all cases.

An indirect laryngoscopic evaluation was performed in all cases. Direct laryngoscopy and histopathological examination were done in required cases.

Thus the clinical diagnosis was made of all the cases with voice problems. Then the 43-item questionnaire of VoiSS and 30-item questionnaire of VHI were applied to all patients. The results and scores of both the voice analysis tools (VoiSS and VHI) were then compared to each other.

All the patients under study were kept under follow up until the proper treatment of voice disorder was carried out. The follow-up period for the different patient was different as the treatment duration for all diseases is not the same.

The patients were assessed thoroughly again, and both the VHI and VoiSS questionnaire were reapplied to all the patients after treatment.

Only those patients who were able to complete the posttreatment questionnaire were included in the study. Laryngectomized and tracheostomized patients were excluded from the study.

The comparisons between pre and post-intervention VHI scores and pre- and post-intervention VoiSS scores as well as between VHI and VoiSS scores were carried out to assess the role of these scores in deciding treatment pattern for the voice disorders as well as in assessing the quality of life of patients of voice disorders.

The improvement in the quality of life following treatment of voice disorder was assessed using the difference between pre and post VHI and VoiSS score.

RESULTS

The maximum number of cases of dysphonia, we encountered was of malignant growth larynx followed by a vocal nodule, globus and so on, as plotted on the following table (Table 3).

Since the cases included in the present study were only those, who were able to complete our questionnaire

Table 1: Voice handicap index

S.No	Questionnaire	Score				
	Part I-F	0	1	2	3	4
1.	My voice makes it difficult for people to hear me.					
2.	People have difficulty understanding me in a noisy room.					
3.	My family has difficulty hearing me when I call them throughout the house.					
4.	I use the phone less often than I would like to.					
5.	I tend to avoid groups of people because of my voice.					
6.	I speak with friends, neighbors, or relatives less often because of my voice.					
7.	People ask me to repeat myself when speaking face-to-face.					
8.	My voice difficulties restrict my personal and social life.					
9.	I feel left out of conversations because of my voice.					
10.	My voice problem causes me to lose income.					
	SUBTOTAL _____					
	Part II-P					
1.	I run out of air when I talk.					
2.	The sound of my voice varies throughout the day.					
3.	People ask, "What's wrong with your voice?"					
4.	My voice sounds creaky and dry.					
5.	I feel as though I have to strain to produce voice.					
6.	The clarity of my voice is unpredictable.					
7.	I try to change my voice to sound different.					
8.	I use a great deal of effort to speak.					
9.	My voice is worse in the evening.					
10.	My voice "gives out" on me in the middle of speaking.					
	SUBTOTAL _____					
	Part II-E					
1.	I am tense when talking to others because of my voice.					
2.	People seem irritated with my voice.					
3.	I find other people don't understand my voice problem.					
4.	My voice problem upsets me.					
5.	I am less outgoing because of my voice problem.					
6.	My voice makes me feels handicapped.					
7.	I feel annoyed when people ask me to repeat.					
8.	I feel embarrassed when people ask me to repeat.					
9.	My voice makes me feel incompetent.					
10.	I am ashamed of my voice problem.					
	Subtotal _____					
	Total _____					

0 = Never, 1 = Almost Never, 2 = Sometimes, 3 = Almost always, 4 = Always

of VHI and VoSS and were supposed to come for the follow up till the intervention for their voice disorder completed, so the data of prevalence of voice disorders may be different than in present study.

In the present study, the prevalence of voice disorders was found to be more in male (60%) patients as compared to female (40%) patient.

Also, the prevalence of cancer larynx and laryngopharynx was found to be more in male and prevalence of globus was more in female patients.

Globus pharyngis, in most cases, is caused by inflammation of one or more parts of the throat, such as the larynx and/or hypopharynx, gastroesophageal reflux disorder, due to cricopharyngeal spasm, laryngo-pharyngeal reflux or oesophageal versatility.[7]

In a few cases, the cause of globus is unknown, and the symptoms may be attributed to a psychogenic cause, i.e., a somatoform or anxiety disorder. It has also been recognized as a symptom of depression, that responds to antidepressive treatment.[8]

Table 2: Voice symptom scale

S.No	Questionnaire	0	1	2	3	4
1.	Do you have difficulty attracting attention?					
2.	Do you get frustrated by your voice problem?					
3.	Do you have problems singing?					
4.	Do people ignore you?					
5.	Is your throat sore?					
6.	Are you able to shout?					
7.	Is your voice hoarse?					
8.	When talking in company do people fail to hear you?					
9.	Do you lose your voice?					
10.	Does your voice problem reduce your social life?					
11.	Are you able to read aloud?					
12.	How often do you worry about catching a throat infection?					
13.	Do you cough or clear your throat?					
14.	Do you have pains in the chest?					
15.	Do you have a weak voice?					
16.	Do you have problems talking on the telephone?					
17.	Do you feel miserable or depressed because of your voice problem?					
18.	Does it feel as if there is something stuck in your throat?					
19.	Do you have swollen glands?					
20.	Do you talk less than you normally would?					
21.	Are you embarrassed by your voice problem?					
22.	Do you find the effort of speaking tiring?					
23.	Does your voice problem make you feel stressed and nervous?					
24.	Do you have difficulty competing against background noise?					
25.	Are you unable to shout or raise your voice?					
26.	Are you able to ask for things in shops?					
27.	Does your voice problem put a strain on your family and friends?					
28.	Do you have a lot of phlegm in your throat?					
29.	Do you run out of air when you talk?					
30.	Does the sound of your voice vary throughout the day?					
31.	Do people seem irritated by your voice?					
32.	Do you have a blocked nose?					
33.	Do people ask what is wrong with your voice?					
34.	Does your voice sound creaky and dry?					
35.	Do you feel you have to strain to produce voice?					
36.	Do you find other people do not understand your voice problem?					
37.	Do you try to change your voice to sound different?					
38.	How often do you get throat infections?

	Total					

0 = Never, 1 = Occasionally, 2 = Some of the time, 3 = Most of the time, 4 = All of the time

A total of 44% of cases examined in the present study were having a history of smoking or alcohol intake.

Moreover, all case of cancer laryux and laryngopharynx were having a history of smoking or alcohol intake or both which significantly proves cigarette smoking and alcohol intake as the important risk factor of cancer larynx and laryngopharynx.[7]

A total of 24% of all cases in the present study were having a history of vocal abuse either due to occupation or due to habit.

All cases of the vocal nodule, vocal cord papilloma, and vocal polyp were having a history of vocal abuse, which is showing the relationship between vocal abuse and development of vocal nodule or polyp.[8] Though vocal cord papilloma is a viral disease and is not associated with vocal abuse, in our case there was a coincidental history of vocal abuse.

Majority of the cases (48%) included in this study were of the age group of 41 to 60 years and the rests were as shown in Table 4.

Table 3: Clinical diagnosis of patients with voice disorders

No.	Diagnosis	No. of cases	Percentage
1.	M.G. larynx	15	30%
2.	Vocal nodule	9	18%
3.	Globus pharyngis	6	12%
4.	M.G. pharynx	5	10%
5.	Laryngitis	5	10%
6.	Pharyngitis	3	6%
7.	Vocal cord palsy	2	4%
8.	Vocal cord polyp	1	2%
9.	Vocal cord papilloma	1	2%
10.	Puberphonia	1	2%
11.	Goitre	1	2%
12.	Acute bronchial Asthma	1	2%
	Total	50	100%

Table 5: Presenting complaints of the patients

S.No.	Presenting complaints	No. of cases	Percentage
1.	Change in voice	35	70
2.	Difficulty in breathing	03	06
3.	Difficulty in swallowing	05	10
4.	Stridor	04	08
5.	Neck swelling	03	06
6.	Total	50	100

The presenting complaint of most of (70%) patients included in the present study, was the change in voice. The change in voice varied from simple harshness in laryngitis to hoarseness in carcinoma larynx. Six percent of the patient came with the complaint of neck swelling associated with dysphonia. 10% of patient were having to present complains of difficulty in swallowing, 8% were having stridor, and 6% patients came with complaints of difficulty in breathing (Table 5).

VHI scores of all the patients both before and after treatment were noted, and also the differe nce between them was calculated (Table 6 and Fig. 1).

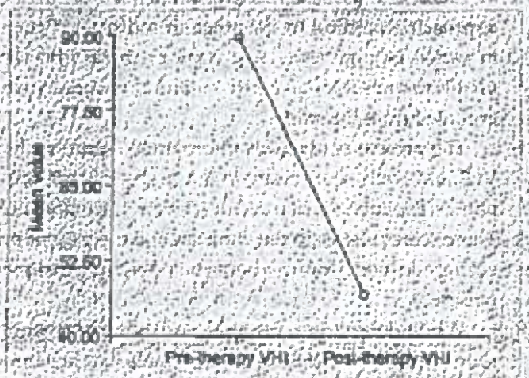

Fig. 1: Plot of mean sections of pre- and post-therapy VHI score

Table 4: Age wise distribution of patients

S. No.	Age-group	No of cases	Percentage
1.	11–20	5	10
2.	21–30	5	10
3.	31–40	8	16
4.	41–50	12	24
5.	51–60	12	24
6.	61–70	07	14
7.	71–80	01	02
	Total	50	100

Table 6: Pre- and post-treatment VHI score

	Pre-treatment VHI score			Post-treatment VHI score			
Total count	Mean	Standard deviation	Standard error	Mean	Standard deviation	Standard error	Mean of difference
50	89.7	26.54	3.75	49.96	29.315	4.14	42.14

Table 7: Pre- and post-treatment VoiSS score

	Pre-treatment VoiSS score			Post-treatment VoiSS score			
Total count	Mean	Standard deviation	Standard error	Mean	Standard deviation	Standard error	Mean of difference
50	119.28	37.98	5.37	83.16	35.32	4.99	58.12

A significant difference between pre- and post-treatment VHI score was found which shows the improvement in the quality of life of the patient after treatment of voice disorder.

Similarly, scores of VoiSS both before and after treatment were also noted and statistical analysis was done (Table 7 and Fig. 2).

In case of VoiSS questionnaire also, a similar type of scores found showed improvement in the quality of life of the patient after treatment of the voice disorder.

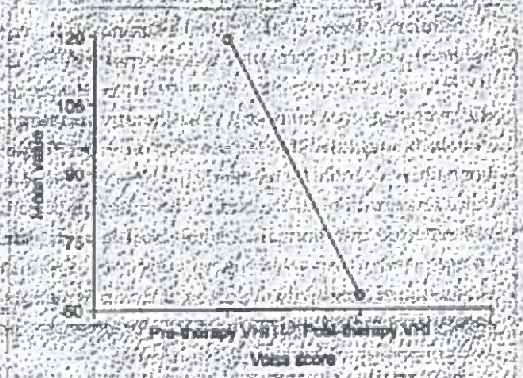

Fig. 2: Plot of mean sections of pre and post therapy VoiSS score

VoiSS score; more is the improvement in the quality of life of the patient.

CONCLUSION

In the present study, the results of both VHI and VoiSS were similar and highly correlated, and the comparative study did not favor any of the scale more for the evaluation purpose.

Thus the study showed that both VHI and VoiSS are important tools to assess the disability caused by voice disorders and also very useful to measure the functional outcomes of medical, behavioral and surgical treatment of voice disorders. These scores help the clinician and the patient to compare various treatment options. The improvement in the quality of life of the patient as well as the effectiveness of various voice intervention can be assessed using these scales.

ABSTRACT

Background: Tympanoplasty, also called eardrum repair, refers to surgery performed to reconstruct a perforated tympanic membrane (eardrum) or the small bones of the middle ear. Eardrum perforation may result from chronic infection or, less commonly, from trauma to the eardrum.

Objective: The Objective of the study is to evaluate the surgical outcomes of tympanoplasties with and without mastoidectomies in terms of graft uptake and hearing improvement.

Methods: A total of 58 patients undergoing tympanoplasties with and without mastoidectomy were included and followed up for a period of one year.

Results: There was no significant difference in the surgical outcomes of both the surgeries in terms of graft uptake and hearing improvement. In inlaid technique Ballast Rule of 3 thumb application enables the actual hearing benefit of the patient.

Conclusion: There is no difference in related to outcome. The addition of cortical mastoidectomy to tympanoplasty did not improve the outcome of surgeries done for mucosal type of chronic suppurative otitis media.

KEY WORDS: Cortical Mastoidectomy, Tympanoplasty, Ballast Rule.

INTRODUCTION

Tympanoplasty, also called eardrum repair, refers to surgery performed to reconstruct a perforated tympanic membrane (eardrum) or the small bones of the middle ear. Eardrum perforation may result from chronic infection or, less commonly, from trauma to the eardrum.

The tympanic membrane of the ear is a three-layer structure. The outer and inner layers consist of epithelium cells. Perforations occur as a result of defects in the middle layer, which contains elastic collagen fibers. Small perforations usually heal spontaneously. However, if the defect is relatively large, or if there is a poor blood supply or an infection during the healing process, spontaneous repair may be hindered. Eardrums may also be perforated as a result of trauma, such as an object in the ear, a slap on the ear, or an explosion [1]. The purpose of tympanoplasty is to repair the perforated eardrum, and sometimes the middle ear bones that consist of the incus, malleus, and stapes. Tympanic membrane grafting may be required. If needed, grafts are usually taken from a vein,

or fascia (muscle sheath) tissue on the lobe of the ear [2]. Synthetic materials may be used if patients have had previous surgeries and have limited graft availability. The mastoid is a honeycomb cavity in the temporal bone, which lies directly behind the ear and is connected to the middle ear space. When a hole arises in the eardrum due to previous injury or infection, or when a long-standing infection persists with tissue in the middle ear or mastoid, mastoid surgery often becomes necessary to alleviate this infection. This part of the procedure is called mastoidectomy. Surgery for tubotympanic type of chronic suppurative otitis media is the commonest otological surgical procedure in our country [3].

This study discusses the various pre-operative factors which play a major role in the post-operative success of two various surgeries – myringoplasty and cortical mastoidectomy with type 1 tympanoplasty. The hearing benefit is determined by Air bone gap closure and also subjective evaluation of hearing is done by applying Belfast rule of thumb.

MATERIALS AND METHODS

This Prospective study was conducted at RNT medical college and attached M B hospital, Udaipur, Rajasthan from Dec 2009 to Dec 2011. Study involves total 56 patients attending ENT OPD with mucosal disease at Our hospital for a period of one year and the patients were followed up for a period of one year. Among them, 6 patients did not turn up for follow up and they were excluded from the study.

Inclusion criteria: Patients between 15 to 50 years of both sexes, after elimination of focal sepsis, having either wet or dry ears and pure tone audiometry showing conductive hearing loss.

Exclusion Criteria: Patients with congenital or acquired abnormalities of ear, unsafe ear, undergone ear surgeries previously and with pure tone audiometry showing mixed and sensorineural hearing loss were excluded from the study.

Methodology: Minimum duration of discharge for the patients under study was 1year and maximum was 15 years. Minimum duration of hearing impairment was 6 months and maximum was 10 years. For all patients, under study with wet ears, ear swabs were taken from middle ear and for patients with culture positive results, treated with specific antibiotics prior to surgery.

All cases were admitted, pre-operative examination done under microscopy, subjected to endoscopic eustachian tube evaluation (those with normally looking pharyngeal end of eustachian tube orifice were taken up for study) and hearing assessment done with tuning fork tests and pure tone audiogram. All patients were informed about their need for a follow up period of one year. Informed written consent to undergo surgery was obtained from all patients. Mastoid shaving and local preparation was done in the ward prior to surgery. All cases were done under GA. Premedication and local infiltration was done for all cases.

Group A: About 25 patients with dry ear for more than 6 weeks and with only conductive hearing loss, were subjected to myringoplasty and considered as Group A. About 13 patients with unilateral disease and 12 patients with bilateral disease were taken up for study. For patients with bilateral disease, worse ear was taken up for surgery. All patients were taken up for surgery under GA. Trans canal approach was followed in 21 cases and in 4 cases with narrow external auditory canal, post aural approach was followed. 4 quadrant local infiltration was given with 2% xylocaine with adrenaline premixed solution. Temporalis fascia graft harvested by a separate incision over supra auricular region for patients done through trans-canal approach & in patients done through post aural approach, graft was harvested via the same incision. Temporalis fascia graft kept by underlay technique. All cases were followed up for 3,6 months and one year for graft uptake and postoperative hearing evaluations done at 3,6 months and one year. Results of hearing benefit, compared with pre-op and post-op air bone gap and for unilateral disease Belfast rule of thumb applied.

Group B: About 25 patients with wet ear and with no active infection as per microbiological report & with conductive hearing loss were subjected to cortical mastoidectomy with type 1

tympanoplasty and considered as Group B. About 15 patients with unilateral disease and 10 patients with bilateral disease were taken up for study. For patients with bilateral disease, worse ear was taken up for surgery.

All patients were taken up for surgery under GA. Post-aural approach was followed in all cases. Post aural incision made, temporalis fascia graft harvested through the superior aspect of the incision as the first step, incision deepened and mastoid cortex exposed. Pinna retracted anteriorly, incision made in the posterior canal wall skin from 6 o'clock to 12 o'clock position and tympanomeatal flap was elevated. Granulations if present in the tympanum were removed, mobility of ossicular chain were checked. Mastoid cortex was drilled out in all cases, patency established. For, about 21 patients granulations noted in antrum removed and in 4 patients antrum found free of disease. For all patients, temporalis fascia graft kept by underlay technique, tympanomeatal flap repositioned and post-aural wound closed in layers. All cases were followed up for 2, 6 months and 1 year for graft uptake and post-operative hearing evaluations done at 3, 6 months and 1 year. Results of hearing benefit, compared with pre-op and post-op air bone gap and for unilateral disease, Belfast rule of thumb applied.

Even though socio-economic status does influence the disease, all the patients attending RNT Medical College and M B Hospital Hospital belongs to lower, socio-economic group. Hence this parameter is not included in this study.

RESULTS

Total number of cases registered in this study was 56 patients, who came to the ENT Department with Mucosal disease. Among them 6 patients did not turn up for follow up and hence they were not included in the study.

The overall graft take up rate in both the surgeries was 88.33%. The overall hearing benefit was 90%, excellent with < 10dB ABG in 51.67% and Good with < 20dB in 38.33%. There was no postoperative complications, deterioration in hearing or sensorineural hearing loss in all 50 patients.

In Group A ,15 were females & 10 were males, 13 patients had unilateral and 12 had bilateral disease, 20 had medium sized central perforation and 05 had subtotal perforation. 10 had good pre-op Air bone gap of 10 to 20 dBHL 15 patients had a fair pre-op Air bone gap of 20 to 30 dBHL.

1. Overall graft take up rate was 86.6%.

2. Otoscopic evaluation of 20 patients with medium sized perforation at the end of 2 months, revealed 15 to be intact, 5 residual perforation in the antero - inferior quadrant. In 5 patients with subtotal perforation 3 were intact, 1 with residual perforation & 1 grafts got rejected because of post-op wound infection. Otoscopic examination at the end of 6months & 1 year revealed – for all 20 patients with medium size perforation, tympanic membrane was intact and out of 5 patients with subtotal 2 were with residual perforation & 1 with rejection of graft. Hence the size of the perforation does have a role in graft take upirate. This is statistically significant by applying chi square test with p value < 0.05.

3. In 10 patients with good pre-op ABG, the post-op ABG was excellent. In 15 patients with fair pre-op ABG, the post-op ABG results were, excellent in 9, good in 8 and fair in 3 patients accounting for 46.66% in excellent, 40% in good and 13% in fair groups. By applying Chi square test, these results are statistically significant. Hence, for the patients with lesser pre-operative Air bone gap have a better post-operative hearing.

4. When Belfast rule of thumb was applied to 13 patients with unilateral disease, 10 of them with medium sized perforation, felt subjectively better and out of 3 of them with subtotal perforation, 2 felt better & 1 patient felt hearing same as the pre operative status. These results are statistically significant with p value<0.05, implies that Belfast rule of thumb interpret the post-operative hearing benefit in a better way than the Air-bone gap ,which tells about only the technical success.

5. The correlation coefficient between the duration of discharge and the pre-op ABG is 0.4172 and that between the duration of hearing impairment with pre-op ABG is 0.3821 and is statistically significant. The correlation coeffi-

-ent between the duration of discharge and the post-op ABG is 0.4544 and that between the duration of hearing impairment with post-op ABG is 0.4489 and is statistically significant, implies that the patients with lesser duration of discharge and hearing impairment had better post-operative hearing than the patients with longer duration of disease and hearing impairment.

6. The other parameters, such as age, sex, weight does not have influence on the outcome of results in this study.

7. The type of approach does not have a significant p value with graft intake in this study. Applying chi square test, the Pearson value is 0.

In Group B, 17 were females & 8 were males, 15 patients had unilateral and 10 had bilateral disease. 18 had medium central perforation and 07 had subtotal perforation, 08 had good pre-op Air bone gap of 10 to 20 dBHL, 17 patients had a fair pre-op Air bone gap of 20 to 30 dBHL.

1. Overall graft take up rate was 96%.

2. The relationship between graft take up rate and size of the perforation is statistically significant by applying chi square test with person value of 0.02535.

Otoscopic evaluation of 15 patients with medium sized perforation at the end of 2 months, revealed 14 to be intact, 1 residual perforation in the antero-inferior quadrant. In 07 patients with subtotal perforation, 05 were intact, 2 with residual perforation. Otoscopic examination at the end of 6 months & 1 year revealed – for all 18 patients with medium size perforation, tympanic membrane was intact and out of 07 patients with subtotal 3 were with residual perforation. Hence the size of the perforation do have a role in graft take up rate even when cortical mastoidectomy is done along with repair of tympanic membrane.

3. In this study, out of 18 patients with medium sized perforation, 8 had a good & 17 had fair pre-op ABG. Out of 07 patients with subtotal perforation, 6 patient had good & 01 had fair pre-op ABG, implies that 85.71 % of the patients with subtotal perforation had pre-op ABG of 20 to 30 dB.

4. Out of 25 patients included in this procedure -re, 50% had excellent, 50% had good &10% had fair post-op ABG. Those with medium sized perforation had better results than those with subtotal perforation.

5. On comparison of pre-op ABG & post-op ABG, all 8 patients with good pre-op ABG improved to excellent, out of 17 with fair ABG, 3 were excellent, 12 were good and 2 were fair post-operatively. This result is highly statistically significant with pearson value of 0.00006

6. Graft intake in 4 patients with disease free antrum mucosa is 100%.

7. Out of 25 patients, 21 patients had disease in the antrum & 4 had a healthy antrum. 77.85% of the patients with healthy antrum and 9.5% of the patients with diseased antrum had good pre-op Air bone gap 30.5% with diseased and 22.2% with healthy antrum had fair preop Air bone gap.

8. In patients with healthy antrum, the post-op ABG was excellent in 88.9% and 66.7% of the patients

with diseased antrum had a good ABG post-operatively.

9. On applying Rellfast rule of thumb to 15 patients with unilateral disease, 83.3% had better hearing, implies the post-operative hearing benefit better than assessment with Air bone gap.

10. The correlation coefficient between the duration of discharge and the pre-op ABG is 0.3803 and that between the duration of hearing impairment with pre-op ABG is 0.3776. The correlation coefficient between the duration of discharge and the post-op ABG is 0.3794 and that between the duration of hearing impairment with pre-op ABG is 0.3729 and are statistically significant, implies that the patients with lesser duration of discharge and hearing impairment had better post-operative hearing than the patients with longer duration of disease and hearing impairment.

11. The other parameters, such as age, sex, weight does not have influence on the outcome of results in this study.

DISCUSSION

Analysis of 50 cases undergone surgery for [illegible]

same is compared with similar and related studies available in literature.

1. Graft Take Up Rate: The overall graft take up rate in Myringoplasty in this study was 86.6%, which is within the range to the studies available. The graft take up rate in various studies were [Table 1].

Table 1: Graft take up rate [1].

Study	No of cases	year	Graft take up rate
Gibb, Cleary R.M [5]	345	1982	91.60%
Black, PJ Wormald [3]	261	1995	78%
Raj A Vidit [2]	50	1999	84%
Kotecha et al [7]	107	1999	82.20%
Tasso, Mishira et al [1]	104	2001	94.60%
Kageyama et al [6]	190	2001	82.30%
Alberra et al [2]	85	2008	86%

The graft take up rate in Cortical mastoidectomy with type 1 tympanoplasty is 90% which is also within the range to the studies available in literature [Table 2].

Table 2: Graft take up rate [2].

Studies	No of cases	Graft take up rate
Tasso, Mishira et al [1]	147	94.20%
Adnan saleem et al [2]	85	92.95 %
Alberra et al [2]	100	91%
Rahi CM et al [2]	135	90.40%

2. Graft Failure Rate: Graft failure rate in various studies were [Table 3].

Table 3: Re-perforation Rate % [1].

Studies	Re-perforation Rate %
Alberra et al [2]	7 to 21
Vartiainen et al [14]	10.6
Adnan, saleem et al [2]	7.05

In this study, in myringoplasty series the rate of residual perforation is 5.7% and the rate of rejection of graft is 6.7%. The probable cause of residual perforation is the slippage of the graft from its position and the cause for rejection is the post operative infection of the operated site, which is same as the reason cited by the study of Vartiainen et al and Kotecha et al [7,14] Study of Alberra et al also includes the efficiency of the surgeon and the surgical techniques [2].

3. Pre-operative Hearing: In this study the pre operative pure tone average in Myringoplasty series was between 30 to 40 dB with average type 1 tympanoplasty series between 30 to 55 dB with average being 42.16 dB. As the perforation size increases, the preoperative hearing threshold also increases – this is consistent with the study conducted by Mehta et al, Bhusal et al Nepal A Bhandary et al, Kageyama et al, Alberra et al and Saeed et al [1,2]

4. Post Operative Hearing Benefit: Hearing improvement in various studies quoted in literature were [Table 4];

Table 4: Hearing Improvement [2,3].

Study	Hearing improvement
Adnan et al [2]	85.88%
Khan et al [1,2]	84.90%
Raj A Vidit et al [2]	68%
Kotecha et al [7]	67%

In this study, the overall post operative hearing benefit based on Air bone gap was 90% with <10 Db in 51.67% and <20db in 38.33%. As hearing benefit is better assessed with the subjective evaluation, in this study we have applied Belfast rule of thumb in patients with unilateral disease. In 23 patients with unilateral disease in Myringoplasty series, 95.7% felt significant improvement in hearing and 4.3% felt no improvement. In 18 patients with unilateral disease in Mastoidectomy with type 1 tympanoplasty series, 83.3% felt significant improvement in hearing and 16.7% felt no improvement.

CONCLUSION

From Our study we Would like to conclude that the success of Myringoplasty in terms of graft uptake and hearing improvement is better in patients with lesser duration of disease, less preoperative Air bone gap and with medium sized perforations when compared to subtotal perforations. The success of Cortical mastoidectomy with type tympanoplasty in terms of graft uptake and hearing improvement is better in patients with lesser duration of disease and less pre-operative Air bone gap.

ABSTRACT

Objectives: The objective of our study was to examine the aerobic bacteriological profile and antibiotic sensitivity pattern to locally available antibiotics in chronic suppurative otitis media (CSOM) in Rajsamand district of Rajasthan state in India.

Materials and methods: This prospective study was conducted in the department of otorhinolaryngology, Aranya Institute of Medical Sciences, Rajsamand for a period of one year from February 2017 to February 2018. Aural swabs were taken on the first day of attendance of the patients to ENT OPD before any local medication was given to the patient, using sterile cotton wool swabs and sterile ear specula and sent for culture and sensitivity.

Results: A total of 150 cases of CSOM were selected for the study out of which 109 cases were of unilateral CSOM and 41 cases were having bilateral disease. Thus, a total of 191 swabs were taken for analysis. Out of 191 swabs processed, microbial growth was seen in 176 samples while 15 samples showed no growth. 121 (68.75%) samples showed mono-microbial growth while 55 (31.25%) samples showed poly-microbial growth. The peak incidence of CSOM was found in the age group 31-45 years (34.66%) followed by age group 16-30 years (27.33%). Females (62%) were more commonly affected than males (38%) and the female: male ratio was 1.6:1. *Pseudomonas aeruginosa (38.63%) was the most commonly isolated bacterial pathogen followed by staphylococcus aureus (35.22%) and Klebsiella sp. (10.22%).*

Conclusion: A thorough and precise knowledge of the etiological agents causing CSOM and their antimicrobial susceptibility is of essential importance for an effective and efficient treatment and thus in further prevention of both complications and development of antibiotic resistance which is becoming more common now a days.

Keywords: Chronic suppurative otitis media, antibiotic resistance, staphylococcus aureus, Amikacin

INTRODUCTION

Chronic suppurative otitis media (CSOM) is a major problem globally since prehistoric times with higher incidence in developing countries because of poor socio-economic status and lack of health education.[1]

CSOM is a long standing infection of a part or whole of the middle ear cleft. Clinically, CSOM is divided into two major types: Tubotympanic CSOM i.e. 'Safe' or 'Benign' type of CSOM and Atticoantral i.e. 'unsafe' or 'dangerous' type of CSOM.[2]

CSOM is found to be the single major cause for conductive deafness (66.3%) and it is also responsible for 1.5% of speech disorders.[3]

The indiscriminate, haphazard and half hearted use of antibiotics and poor follow up of the patients have resulted in

persistent changes in the bacteriological pattern of the disease, the advent of new antimicrobials, anti-inflammatory and anti-histamine agents make an evaluation of bacterial flora of CSOM important. [4]

The objective of our study was to examine the bacteriological profile and antibiotic sensitivity pattern to locally available antibiotics in CSOM.

MATERIALS AND METHODS

This prospective study was conducted in the department of otorhinolaryngology, Ananta Institute of Medical Sciences, Rajsamand for a period of one year from February 2017 to February 2018.

Aural swabs were taken on the first day of attendance of the patients to ENT OPD before any local medication was given to the patient, using sterile cotton wool swabs and sterile ear speculs. The collected samples were enclosed in airtight plastic tubing and then transported to the microbiology test laboratory. The samples were always taken before cleaning/suctioning the ear canals of the excess purulent exudates. Samples from bilaterally discharging ears were collected separately. The material was inoculated on Sheep Blood agar, Mac Conkey's agar, Chocolate agar, Robertson's Cooked meat broth for aerobic and anaerobic bacteria. The swabs were incubated for 48 hr and 72hr. Organisms were identified using standard procedures. [5] Antimicrobial sensitivity testing for aerobic isolates was carried out by Kirby Bauer disc diffusion method on Muller Hinton agar. Results were interpreted in accordance with central laboratory standards institute guide-lines. [6]

RESULTS

A total of 150 cases of CSOM were selected for the study out of which 109 cases were of unilateral CSOM and 41 cases were having bilateral disease. Thus, a total of 191 swabs were taken for analysis.

Out of 191 swabs processed, microbial growth was seen in 176 samples while 15 samples showed no growth. 121 (68.75%) samples showed mono-microbial growth while 55 (31.25%) samples showed poly-microbial growth.

In present study, age of the patients ranges from 10 months to 73 years. The peak incidence of CSOM was found in the age group 31-45 years (34.66%) followed by age group 16-30 years (27.33%). Females (62%) were more commonly affected than males (38%) and the female: male ratio was 1.6:1. (table.1)

Microbiological profile of isolates from patients of CSOM and their antibiotic sensitivity pattern is depicted in table.2 and table.3 respectively.

Table.1 Age wise distribution of patients with CSOM.

S.No.	Age group (years)	Number	Unilateral	Bilateral	Mono-microbial	Poly-microbial	Sterile	Total
1.	10-15	23	11	12	22	9	4	35
2.	16-30	41	34	7	33	12	3	48
3.	31-45	52	44	8	38	17	5	60

1.	Pseudomonas aeruginosa	68	38.63
2.	Staphylococcus aureus	62	35.22
3.	Klebsiella sp.	18	10.22
4.	Proteus mirabilis	17	09.65
5.	E.coli	8	04.54
6.	Enterococcus faecalis	3	01.70
	Total	176	100

Table 3 Antibiotic sensitivity pattern of organism isolated in present study

S.No.	Antibiotic	Pseudomonas sp.	Staph. Aureus	Klebsiella sp.	Proteus mirabilis	E. coli	Enterococcus faecalis
1.	Ampicillin	0	11 (17.74%)	0	0	0	0
2.	Cloxacillin	0	18 (27.41%)	0	0	0	0
3.	Ampicillin + clavulanate	0	48 (77.41%)	0	0	0	0
4.	Amikacin	59 (86.76%)	38 (61.29%)	8 (44.44%)	7 (41.17%)	4(36%)	0
5.	Gentamicin	47 (69.11%)	39 (62.90%)	2 (11.11%)	3 (17.64%)	0	0
6.	Netilmicin	48 (70.58%)	42 (67.74%)	0	3 (17.64%)	2 (22%)	0
7.	Vancomycin	64 (94.11%)	47 (75.80%)	0	0	0	0
8.	Ciprofloxacin	38 (55.88%)	22 (35.48%)	6 (33.33%)	3 (17.64%)	3(31.3%)	1 (33.3%)
9.	Levofloxacin	36 (44.11%)	15 (24.19%)	4 (22.22%)	2 (11.76%)	1(12.5%)	1 (33.3%)
10.	Ceftriaxone	4 (60.29%)	44 (70.96%)	2 (11.11%)	3 (17.64%)	4(50%)	0 (66.66%)
11.	Cefotaxime	27 (39.70%)	28 (41.93%)	1(5.55%)	3 (17.64%)	3(37.5%)	0
12.	Ceftazidime	5 (7.3%)	44 (70.96%)	1(5.55%)	9 (52.94%)	0	0
13.	Piperacillin+ Tazobactam	51(75%)	53 (85.50%)	6 (33.33%)	6 (35.29%)	3(41.3%)	1 (33.3%)

DISCUSSION

CSOM is a long standing infection of a part or whole of the middle ear cleft. Clinically, CSOM is divided into two major types: Tubotympanic CSOM i.e. 'Safe' or 'Benign' type of CSOM and Atticoantral i.e. 'unsafe' or 'dangerous' type of CSOM. [2]

The definitive treatment of CSOM is by surgery (tympanoplasty and/or mastoidectomy), nevertheless, initial treatment by ear toilet and ototopical agents is necessary to prepare the ear for surgery. The selection of local or systemic antibiotic for therapy depends greatly on the type of the organism isolated in such cases.

In present study, microbial growth was seen in 176 (92.14%) samples out of 191 swabs used. 15 samples (7.8%) showed no growth. The culture results are found correlated with previous studies. [7-11] Negative cultures can be attributed to Non-bacterial growth, Anaerobic growth, Prior-antibiotic therapy and/ or Presence of antimicrobial enzymes i.e. lysozyme alone or in combination with immunoglobulins that suppress the bacterial growth. [4,10]

121 (68.75%) samples showed mono-microbial growth while 55 (31.25%) samples showed poly-microbial growth. Our study is correlated with Rama Rao et al. (1980) [9] found equal incidence of mixed and pure culture and Barnak et al. (1972) [12] found predominance of mixed culture.

In present study, most commonly affected age group was 31-45 years (34.66%) followed by age group 16-30 years (27.33%). In most of the earlier studies, the most commonly affected age group is 0-30 years. [13-16] The reason for high prevalence in higher age group in present study may be because of low socioeconomic status and poor awareness of the patients in villages near the hospital.

In the present study, Pseudomonas aeruginosa (38.63%) was the most commonly isolated bacterial pathogen followed by staphylococcus aureus (35.22%) and klebsiella sp. (10.22%).

Pseudomonas is the predominant cause of CSOM in tropical region does not usually inhabit the upper respiratory tract, its presence in the middle-ear cannot be ascribed to an invasion through eustachian tube and it should be considered as secondary invader gaining access to the middle-ear via tympanic membrane perforation. [17] Proteus mirabilis was seen in 9.65%% of the cases and Escherichia coli were isolated from 4.5% cases, and these findings were similar to the reports in earlier studies. [14,16]

In the present study the most effective antibiotic against Pseudomonas aeruginosa was found to be Vancomycin (94.11%) followed by amikacin (86.76%), piperacillin+Tazobactam, ceftazidime, netilmicin, Gentamicin, ceftriaxone and ciprofloxacin. This finding was corroborated by studies of numerous other authors. [13,18,19]

Staphylococcus aureus was found to be the second most common organism in the present study. The antimicrobial susceptibility pattern of Staphylococcus

aureus revealed highest sensitivity to piperacillin+tazobactam (88.70%) followed by amoxicillin+ clavulanate (77.41%), Vancomycin (75.80%), ceftriaxone & ceftazidime (70.96%), Netilmicin (67.74%) and Amikacin (61.29%) and least sensitivity to quinolones. In case of Klebsiella sp, Proteus, E.coli and Enterococcus faecalis-ceftriaxone, Amikacin and piperacillin with Tazobactam were found to be equally effective. These findings are in accordance with previous study done by Gulati et al (1997). [9]

CONCLUSION

A thorough and precise knowledge of the etiological agents causing CSOM and their antimicrobial susceptibility is of essential importance for an effective and efficient treatment and also in further prevention of both complications and development of antibiotic resistance which is becoming more common now a days.

Acute Fibrinous and Organizing Pneumonia—A Rare Lung Pathology

Jyotsna Naresh Bharti, MD/DNB Pathology, B. Tulasi Satyendra, MD Pathology,**
Raghvendra Singh Shekhawat, MD Forensic Medicine,† and Asharam Gorchiya, MD Forensic Medicine†

(*Am J Forensic Med Pathol* 2021;00: 00–00)

CASE BACKGROUND

A 37-year-old man had an alleged history of assault with brick on his neck. The patient was brought to the hospital with complaints of fever, shortness of breath, and later, he developed a loss of power in the upper and lower limbs. The patient was managed with a Philadelphia neck collar, intravenous (IV) fluids, tracheostomy, mechanical ventilation, cervical traction, and inotropic support for neurogenic shock and IV antibiotics. Within a week, the patient developed bedsore, ARDS, and ventilator-associated pneumonia. The patient's condition deteriorated, and the patient was declared dead on the 20th day of hospital admission. Both the lungs weighed 972 and 994 g, respectively. The lungs were edematous and showed blackish discoloration on the surface. The cut section of both the lungs showed congestion and scattered areas of consolidation. There was an expulsion of thick mucoid material on manual compression (Fig. 1). The brain weighed 1194 g, and the cut section showed mild congestion. The vertebral column was accessed by the anterior approach, and the body of the C5 to C6 vertebrae showed fracture dislocation. The spinal cord from C1 to T1 did not show any gross abnormality.

The microscopic examination from both the lungs showed a patchy distribution of intra-alveolar fibrin balls, which involved more than 50% of the alveolar spaces (Fig. 2). There was interstitial expansion by vascular congestion and inflammatory cells. The loose plugs of the fibroblastic collagen matrix, that is, Masson bodies, were also present (Fig. 3). The features were of acute fibrinous organizing pneumonia. However, there was no evidence of aspirated material, hyaline membrane, eosinophilic or granulomatous inflammation, and vasculitis. Special stains were negative for bacteria, fungus, and acid-fast bacilli. Samples for culture were taken from the patient, while alive and at the time of autopsy, showed no growth.

The cerebral hemisphere and cerebellum with brain stem measured 18 × 14 × 8 cm and 11 × 10 × 3 cm and weighed 1050 and 137 g. Grossly, no hemorrhage or infarct was identified both on the surface and on serial slicing. Sections from the cerebral cortex and cerebellum showed only vascular congestion, whereas pons and medulla, and focal areas in the midbrain showed swollen neuronal cell bodies, central chromatolysis from the peripheral dispersion of nissl substance in eosinophilic cytoplasm with the absence of nuclei, that is, red neurons. Few axons showed variable segmental and irregular thickening (Fig. 4). Axonal injury was seen in the focal areas of the midbrain, pons, and medulla.

The part of the spinal cord measured 11 cm in length and weighed 9.5 g. The spinal cord showed marked degeneration of gray matter, total loss of all neuronal cell bodies along the length (Fig. 5). The preserved white matter showed features of axonal injury, that is, axon spheroids, retraction balls, and axons with variable diameters. Axons with empty and filled myelin sheaths were present (Fig. 6). The spinal cord showed sheets of histiocytes (Fig. 7). The present case report highlights an acute clinical condition of spinal shock with respiratory failure as the immediate cause of death. However, the antecedent cause of death was blunt force trauma to the C-spine and the manner of death was a homicide.

DISCUSSION

Beasley, in 2002, first described the acute fibrinous and organizing pneumonia (AFOP) in a series of lung injury patients.[1] Acute fibrinous and organizing pneumonia is a rare histological pattern of interstitial pneumonia with acute or subacute clinical presentation. The acute and fulminant course typically leads to respiratory failure and death, and the patients requiring mechanical ventilation are associated with poor outcomes, like in the present case.[1, 2]

Acute fibrinous and organizing pneumonia has been associated with collagen vascular disorders, autoimmune disorders, transplantation, bacterial or viral infection, acute respiratory distress syndrome, exposure to few drugs, occupational/environmental exposures, and it may be idiopathic also.[3]

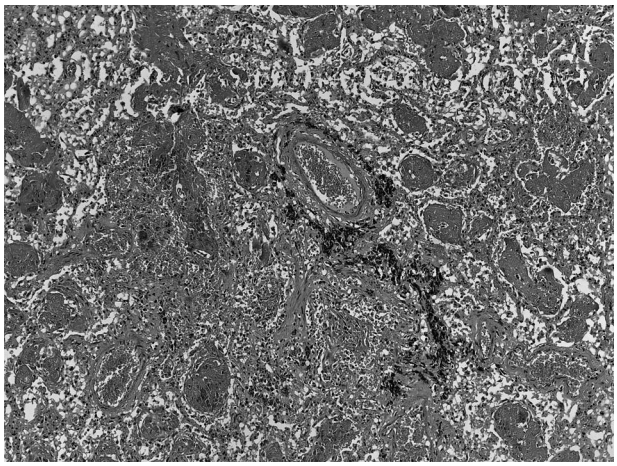

FIGURE 2. Fibrin balls in many alveoli and anthracotic laden macrophages [H&E, 40×].

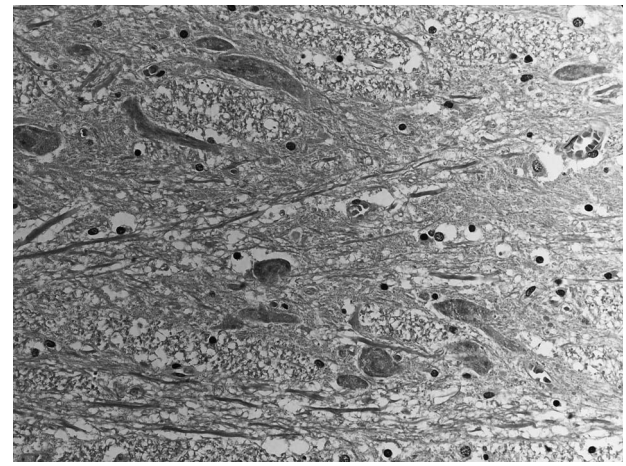

FIGURE 4. Red neuron admixed with variable diameter of axons (H&E, 40×).

Acute fibrinous and organizing pneumonia is characterized by patchy distribution of the intra-alveolar plugs of fibrin deposition, loose intraluminal connective tissue within the alveolar ducts and bronchioles, type 2 pneumocyte hyperplasia and/or minimal edematous interstitial inflammation and widening in an area adjacent to intra-alveolar fibrin with intervening parenchyma showing minimal changes. Acute fibrinous and organizing pneumonia confirmation depends on the biopsy.[1]

Acute fibrinous and organizing pneumonia clinical and histopathological features overlap with diffuse alveolar damage (DAD), cryptogenic organizing pneumonia, and eosinophilic pneumonia. All have different outcomes and well-established morphological criteria, making them distinct entities. Acute fibrinous and organizing pneumonia must be distinguished from DAD and cryptogenic organizing pneumonia, which shows hyaline membranes and fibromyxoid tissue loose plugs. The diffuse in DAD refers to the damage to all elements of the alveolus, and the histological changes are seen throughout the lung parenchyma. The eosinophilic pneumonia is characterized by prominent eosinophilic infiltrates. The clinical course may vary from complete recovery to rapid progression and death.[4] However, the present case was treated as ventilator-associated pneumonia and was put on IV antibiotics. At no point in time, he was given steroids. To date, the treatment for AFOP remains controversial and both steroids and immunosuppressive agents have been reported with favorable outcomes, but patients with advanced age may experience side effects.[1]

It is important for forensic pathologists to be familiar with the AFOP pattern simply to recognize that a severe acute lung injury has occurred, and a forensic pathologist should approach a case showing AFOP in a manner identical to a case showing DAD. In fact, many in the field consider AFOP to simply represent a variant form of DAD.

Cases showing AFOP mandate an appropriate workup for infection like special stains for microorganisms, a search for aspirated material, and microbiologic cultures if possible, and evaluation for other potential causes of severe acute lung injury, for example, an adverse drug reaction, or acute flare of autoimmune disease and occupational/environmental exposures.

The spinal cord injury at any spinal segment can result in respiratory impairment because of respiratory muscle's dysfunctional activity. This is mainly because of the interruption of bulbospinal respiratory projections to phrenic motor neuron groups in the third and fifth cervical regions,[5] whereas the neurogenic shock mainly results in hemodynamic compromise.[6] Most of the patients with injuries of the brainstem and upper cervical

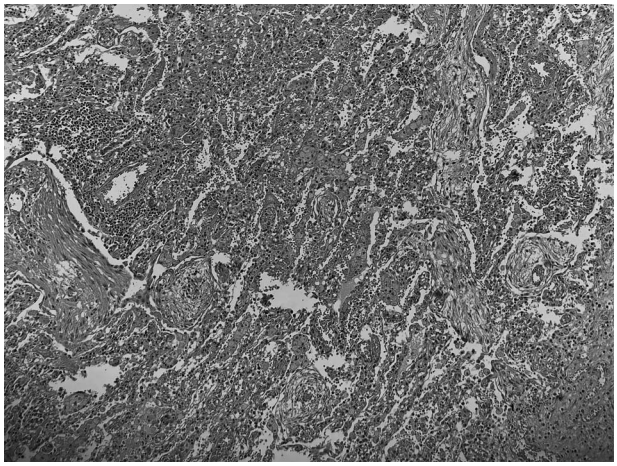

FIGURE 3. Loose plugs of fibroblastic collagen (Masson bodies) (H&E, 40×].

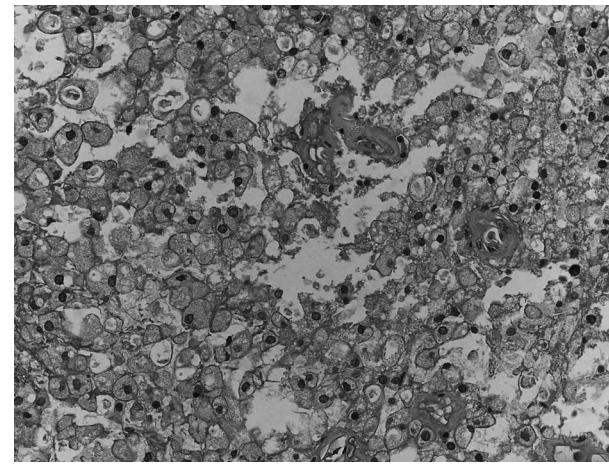

FIGURE 7. Sheets of macrophages (H&E, 40×).

spinal cord die instantly;[7] however, exceptional cases may survive.[8] The neuropathological events in spinal cord injury are infarction, axonal damage, and maybe the perseveration of white matter at periphery at the level of injury. Sheets of macrophage clear the debris. Late sequelae include replacement by collagenous scar, Wallerian degeneration of pathways, nerve root proliferation, spinal stenosis, and posttraumatic syringomyelia, manifesting many years after the initial injury.[9]

CONCLUSIONS

Acute fibrinous and organizing pneumonia is an uncommon pattern of acute lung injury, with a broad differential diagnosis. Acute fibrinous and organizing pneumonia has a variable course, depending on the underlying etiology. It should be included in the differential diagnosis in diffuse lung diseases with respiratory failure with or without shock. Spinal cord injury may lead to spinal and neurogenic shock resulting in morbidity or mortality, depending on the injury's level and extent.

KEY FEATURES

- Very positive students' feedback
- A concise but comprehensive & self contained book
- Full of headings, sub-headings & tables
- Simple & easily understandable language
- Clinically oriented, lucid & Student friendly
- Designed for easy retention of difficult concepts
- Ensures proper preparation for examinations
- Helps prepare MCQs & Viva

ABSTRACT

Gun violence is one of the important indicators of level of social and mental health. It is a global problem and causes considerable hazards in a developing country like India, where poverty and violence are not uncommon. Firearms and their use are modifiable risk factors, which if recognized and addressed, could help decrease the burden of violent death. Our Hospital based Descriptive Observational Study was aimed to assess the socio-demographic parameters of firearm injuries cases in North-Western India, conducted at the Department of Forensic Medicine S.M.S. Medical College, Jaipur during May 2014 to October 2015 period. The burden of gunshot violence is 0.49% (115 cases). Males outnumber females (9:1). Majority of victims were in the second and third decade age group. Incidence is higher in married, literate and rural population. Homicides were the most common manner of death. Property disputes, revenge, robbery are common underlying factors. Educational efforts, individual and community approaches are needed to alleviate firearm injuries. The epidemiologic reviews in this research shall enhance our understanding of various forms of gun violence, inform interventions, and help chart directions for future research.

Key Words: Firearm, Gun-Violence, Homicide, Jaipur

1. INTRODUCTION

Gun violence is violence committed with the handling of a gun (firearm or small arm).[1] It is a global problem and causes considerable hazards in a developing country like India, where poverty and violence are common. The World Health Organization (W.H.O.) report on violence invokes member nations to scientifically and comprehensively adopt tactics to address this global health problem.[2] The estimated total number of guns (both licit and illicit) held by civilians in India is 40 million.[3] This probably explains that gunshot injuries in civilian environment in recent years have increased considerably in various parts of India with wide regional variations. Such injuries have a serious psychological and social impact on the family and community. Medical, legal and emotional costs of such violence impose an enormous burden on urban and rural hospitals, court of law, families, and the society as a whole.

Firearms and their use are modifiable risk factors, which if recognized and addressed, could help decrease the burden of violent death.[4]

Many researchers have studied the various aspects of the firearm injuries in different part of the world. The incidence of Gun violence is increasing day by day in north-western India (Jaipur-region) yet scanty of data is available. Our pioneer study is aimed to assess the socio-demographic parameters of firearm injuries cases in this region.

2. MATERIAL & METHOD

Descriptive Observational Study carried out during May 2014 to October 2015 at the Department of Forensic Medicine and Toxicology, S.M.S. Medical College and attached hospitals, Jaipur. All fatal and non-fatal medico-legal cases of firearm injuries reported at the study setting. Inclusion criteria include firearm injuries cases admitted for treatment purpose in the hospital and cases undergone for autopsy at the departmental mortuary.

Air gun injuries cases, explosion injuries cases and cases that did not provide informed written consent for the study were the exclusion criteria. A pre-validated questionnaire was developed to record socio-demographic data pertaining to firearm injury cases. The investigator contacted the subject and informed about the purpose of the study. A legally valid well informed written consent was obtained from patients themselves or from nearest relative, in case of subjects those who were recruited from the mortuary. The questionnaire included information on age, sex, marital status, residence, occupation, education, outcome (survival or death) and motive behind incidence happened. Data were entered in MS excel sheet and descriptive statistical analysis was done. Ethical clearance for the study was obtained from Institute Ethics Committee of S.M.S. Medical College, and attached group of Hospitals, Jaipur.

3 RESULTS

A total of 23,584 medico-legal cases were reported during study period at the Department of Forensic Medicine, S.M.S. Medical College and attached Hospital, Jaipur. Among them 115 cases were concluded to be of firearm injuries with a burden of 0.49 %. About 67% of cases were from 20-39 years of age with peak incidence in age group of twenties (38%) and mean age was concluded 31.45 years. Male victims (about 90% cases) predominated over females (as illustrated in table 1). Married population sharing 80% of the study population affected with gun-violence. 89% cases belong to rural region. Most of victims (79% cases) were literate and rest was illiterate.

Table 1

Age and Sex Wise Distribution of Victims of Firearm Injuries (N= 115)

Age group (in yrs)	No. of Males Victims	No. of Females Victims	Total No. of Victims	Percentage of Victims
<10	01	01	02	1.74
10-19	08	01	09	7.83
20-29	42	02	44	38.26
30-39	28	05	33	28.70
40-49	13	01	14	12.17
50-59	09	02	11	9.57
> 60	02	00	02	1.74
Total	**103 (89.57%)**	**12 (10.43%)**	**115**	**100**

Table 2

Distribution of Victims of Firearm Injuries according to the Motive behind the gun-shot injuries (GSI) (N= 115)

Motive behind GSI	Number of cases	Percentage
Property disputes	49	42.61
Revenge	16	13.91
Robbery	14	12.17
Unknown	12	10.43
Accidental (no motive)	10	08.70
Group Quarrel	08	06.96
Love Affair	03	02.61
Defense	03	02.61
Grand Total	**115**	**100**

Agriculture was the most common occupation of victims of gun-shot injuries followed by self-employed people (as displayed in figure 1). Majority of the incidences of gun-shot injuries were homicidal in nature (78%) followed by accidental episodes (16.5%)

Surprisingly, there were only 2 cases of suicidal gun- shot injury. Property disputes were the most common motive behind firearm injuries followed by revenge (as shown in table 2).

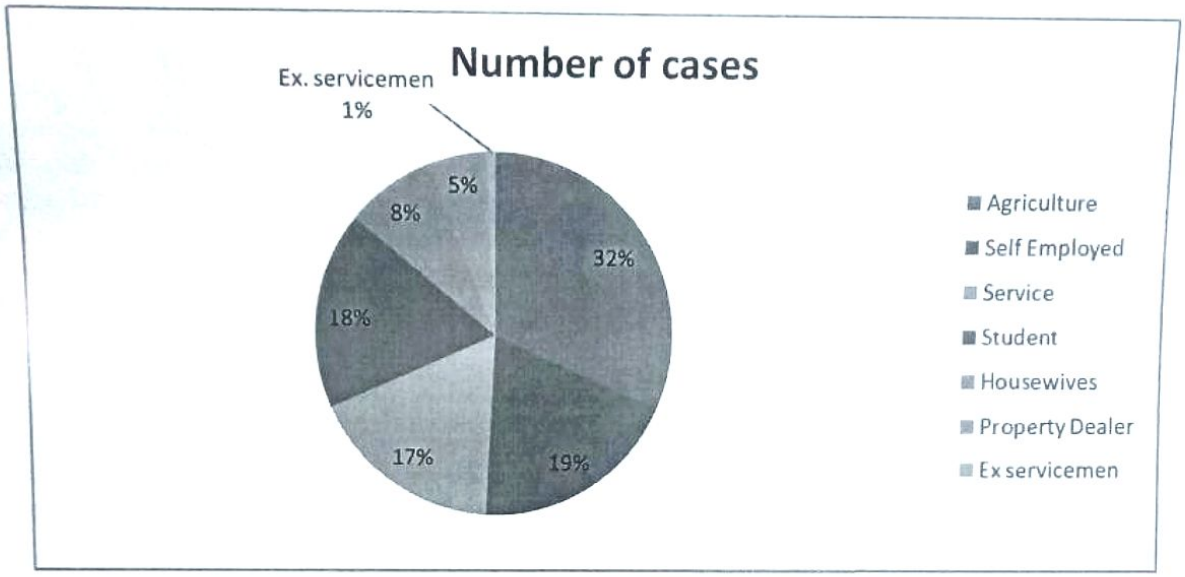

Figure 1
Distribution of Victim of Firearm Injuries according to Occupational Status (N= 115)

4. DISCUSSION

Present study was conducted at the tertiary health care centre situated in Jaipur which provides health care to large number of referral population of the various districts of Rajasthan as well as other adjoining states of Haryana, Uttar Pradesh, Madhya Pradesh and Bihar

During study period 23,584 medico-legal cases were received at the Department of Forensic Medicine. Out of these 115 cases were of gunshot injuries with burden of 0.49%. A total of 5,135 autopsies were conducted and among them 11 cases (0.22%) were fatal firearm injuries. This is quite less as compared to other past studies of Patowary A[5], Kumar P et al[6], Mehmat T et al[7], Capt Mirza F et al [8], Kumari S[9] but similar to other researchers viz Amiri A. et al [10], Sachan R et al [11], Shashikant VK et al [12], Chaurasia N[13], Davies MJ et al [14], Rao D [15]). The reason for this great variation owes to the geographical variations in the different places of study.

In the present study maximum numbers of cases were from 20-39 years of age (66.96%) with peak incidence in age group of twenties (38.26%) which are the reproductive and active members of the society. The observations of the present study were similar to those of Patowary A [5], Kumar P et al[6], Sachan R et al[11], Shashikant VK et al[12], Chaurasia N[13] (peak incidence between 21-40 years of age in all). However, the results of the present study are variable from those of Kumari S[9]. The probable reason for this variation is the minor cultural and periodical differences as most other studies from the same state.

Males (89.57%) outnumbered the females (10.43%) with a male: female ratio of about 8.9:1 .Similar results have been reported by Patowary A[5] (88.9% males) and Kumari S[9] (90% males). Males are the active participants of the society and more commonly engaged in outdoor activities. Moreover, they are more prone to episodes of rage and revenge. This explains the male preponderance in all studies.

About 80% victims of both sexes were married in the present study. It bears no correlation with such incidences but any type of outrageous behaviour is more common after marriage due to the burden of responsibilities that come hand in hand with it.

The victims of firearm injuries showed a rural preponderance (88.70%) while 11.30% victims belong to urban population. Chaurasia N [13] also showed preponderance of rural victims with slight variations in proportions of the two (72.9& rural & 27.1% urban victims) in both studies. Rural preponderance (46.3%) was also reported by Shashikant VK et al [12]. This is probably due to the easy availability of illegal firearms in rural regions owing to easier violation of laws. It is difficult to implement strict laws in rural

Naveen K. Simatwal,

Medical Science, 2017, 21(85), 137-142,
www.discoveryjournals.com

areas for many reasons, like large area, lower literacy rates, cultural influences, socio-political constraints etc. also, there are more disputes regarding land and property, honor and prestige issues, caste conflicts, social strictures, etc in villages as compared to modern cities, thus resulting in outrage and quarrel are more often.

The literacy status of our study population is high. It is expected from educated people to use such deadly weapons judiciously However the literacy rates are not an indicator of the level of education. Educational status has not been described as a variable in most studies

Among the occupational status of the victims, it was observed that agriculture was the most common occupation among victims (31.30%) which is quite obvious owing to the preponderance of rural population in this study. The higher numbers of persons from agricultural field is also attributable to the fact that land is an important cause of disputes leading to such heinous crimes either in impulse or with planning. Our results are also in accordance with those of Shashikant VK et al [12].

Homicides (78.26%) were the most common manner of firearm injuries in the present study followed by accidental and suicidal pattern. Similar observations were concluded by other researches of Kumari S[9] (88.34%),Sachan R et al [11] (92%) and Chaurasia N [13] (85.4%) . Studies of Patowary A [5] and Kumar P et al [6] have restricted study of only homicidal pattern or suicidal firearm injuries (Rao D [15]) The preponderance of homicide in gun-shot injuries is explainable as these deadly weapons are generally used in planned manner assault or impulsively

Land and property disputes were the most common reason behind firearm injuries in this study (42.61%) followed by revenge & robbery (13.91% & 12.17% respectively);

According to Patowary A [5] and Kumar P et al[6] most cases were due to militant activities, encounters, riots, robberies or family quarrel. This variation from our study is due to the regional variations in the areas of study as Guwahati and Imphal are militant activity prone areas. The results of the present study are quite similar to those of

Sachan R et al [11] who reported 29.51% gun-shot injuries due to property disputes. 21.1% for dacoity. But in slight variation to those of Chaurasia N [13] where maximum (53 %) homicides occurred for personal enmity.

5 CONCLUSSION AND RECOMMENDATIONS

- The firearm homicide in Jaipur region is drastically increasing which is an eye opener to the Indian society.
- Our study conclusive of certain transformations may reduce the mortality, morbidity, and economical loss to the community.
- Inspection of Public health model to curb the gun violence.
- Indian Gun policy regarding armed violence prevention, gun control laws and the small arms trade needs improvisation.
- Young males of the population must be targeted for lifestyle adjustments such as training to refrain from anger or disputes and to prevent the easy access of firearms as a weapon to settle disputes.
- It is applicable to examine that sloppy firearm control is a great contributor to civilian gunshot injuries.
- Higher percentage of unemployment and poverty may be granting to the raised incidence of youth agitation, armed wrongdoing and related gunshot assaults.
- Strong laws are required to provide competent security for the brimming population.
- Promote access to adequate mental health services.

SUMMARY OF RESEARCH

1 Gun violence is a global health hazard.

2 Firearms and their use are modifiable risk factors, which if recognized and addressed, could help decrease the burden of violent death.

3.Educational efforts and individual, community approaches are needed to alleviate gun violence.

FUTURE ISSUES

The epidemiologic reviews in this research enhance our understanding of various forms of gun violence, inform interventions, and help chart directions for future research.

Assessment of Load and Medico-legal Profile of Firearm Injuries and Associated Deaths at SMS Hospital, Jaipur During the Year 2014-2015

Shantilal Pargi[1], R K Punia[2], N L Disania[3], Priyanka Sharma[3]

[1]Third Year Resident, [2]Professor & Head, [3]Assistant Professor, Dept. of Forensic Medicine, SMS Medical College and Hospital Jaipur

ABSTRACT

Background: Gun shot injuries are a great challenge for medical professionals because of high mortality rate. Survival of victim depends upon the extent of damage and promptness of medical services.

Objective: Present study was undertaken to analyse medico-legal aspects of fatal gunshot injuries to provide data in Jaipur region.

Study Type: Hospital based Descriptive Observational Study.

Place and Duration : Department of Forensic Medicine and Toxicology , SMS Medical College and attached hospitals, Jaipur (A tertiary health care centre in north-western INDIA) during the study period of 17 months (May 2014 to October 2015) .

Observation and Results: Out of 23,584 registered medico-legal cases 115 were cases of gunshot injuries with burden of 0.49%. 11 cases were of fatal out of 5135 autopsies conducted. 05 fatal cases died within 6 hours , Homicides were the most common manner of incidence, Rifled firearm weapons were the preferred employed firearm weapon , more than half cases of distant fires were the offending shot in the present study.

Conclusion: Rifled firearm weapons were the most commonly employed firearm weapon. Coma and Shock resulting from gunshot injuries were the cause of death in most fatal cases.

Keywords: *Firearm Injuries, Singeing, Abrasion Collar, Hemorrhagic Shock*

INTRODUCTION

Firearm is any instrument or device designed to propel a projectile by means of explosion of gases generated by combustion of an explosive substance.[1] Firearm (FA) injuries pose great health burden and presents enormous challenge for health and national economies.[2] Firearm are the most dreaded killing tool used by human being. Firearm injury is a global problem and causes considerable problems in a developing country like ours, where poverty and violence are common. External injuries seen trivial but majority of them prove fatal due to extensive damage of vital organs and major blood vessels. In this study the medico-legal aspects of Gunshot injuries were studied in the cases brought to SMS hospital Jaipur for injury report or post-mortem examination.

MATERIAL & METHOD

Study design: This descriptive observational study was carried out during May, 2014 to October, 2015.

Study setting: The study setting was the Department of Forensic Medicine and Toxicology, SMS Medical College and attached Hospitals, Jaipur. This is the largest public hospital of the Rajasthan state which is situated in the Capital of Rajasthan.

Study subjects: All fatal and non-fatal medico-legal cases of firearm injuries reported the Department

of Forensic Medicine and Toxicology, SMS Medical College and attached Hospitals, Jaipur.

Inclusion criteria

1.Cases admitted for treatment.

2.Cases whose autopsy was done in the mortuary of the Department of Forensic Medicine & Toxicology.

Exclusion criteria

1.cases of air gun injuries

2.cases of explosion injuries and

3.cases whose informed written consent was not undertaken.

Study tool

A questionnaire was developed and pre-tested to record type of injury / firearm, outcome (in case, the subject admitted for treatment) and motive behind firearm injury.

Data collection

The investigator contacted the subject, and informed about the purpose of the study and obtained informed written consent from patients themselves, or from nearest relative, in case of subjects those who were recruited from the mortuary.

The questionnaire included information on age, sex, marital status, residence occupation, education, outcome (survival/ death), duration of survival after admission, and motive behind accident happened.

Analysis

Data were entered in MS excel sheet and descriptive statistical analysis was done.

OBSERVATION & RESULTS

9.57% of all firearm cases died and 90.43% survived and discharged routinely after appropriate treatment. Among the 11 fatal cases, about half of the cases died within 0-6 hours including 3 spot deaths. Only single patient survived for more than 3 days. 18% patients died within 6 to 24 hours after the incidence. 27% cases died within 1-3 days after the incidence.

TABLE 1: Distribution of Victims according to their Duration of Survival after sustaining the Gun-shot injuries (N= 11)

Duration of survival in fatal cases	Number of Cases	Percentage
0-6 hours	05	45.45
6-24 hours	02	18.18
1-3 days	03	27.27
>3 days	01	09.09
Total	**11**	**100**

Majority of the incidences of gun-shot injuries were homicidal in nature (78.26%) followed by accidental episodes. 2 cases were of suicidal gun- shot injury. Rifled weapon were most commonly used weapon in about 72% cases. Shotgun was employed for fire arm injuries in 27.83% cases.

Table 2: Distribution According to Type of Firearm Weapons used for offending the victims N= 115

Type of Weapon	Total No. of cases	Non fatal cases	Fatal cases	%
Rifled firearm weapon	83	72	11	72.17
Smooth bore fire arm weapon	32	32	00	27.83
Grand Total	**115**	**104**	**11**	**100**

Incidences of rifled firearm weapons were fatal in 13.25% cases. None of the victim offended with shotguns succumbed to it. Rifled fire arm weapons were significantly related to fatality.

In majority of the cases, gun-shot injuries was fired from distant range (52.17%) and in another major lot of cases, the range remained undetermined (36.52%); possibly may be deciphered in conjunction with a ballistic expert. 6.96% cases were of contact fire, 3.48% of close and a single case (0.87%) of near range of fire.

Table 3: Distribution according to the range of Fire Arm Weapon Used for offending

N= 115

Range of Fire	No. of Cases	Percentage
Distant	60	52.17
Not Determined	42	36.52
Contact	08	6.96
Close	04	3.48
Near	01	0.87
Total	**115**	**100**

In 45.5% cases hemorrhagic shock was the cause of death which was equally contributed by coma in 5 cases. Only one victim died due to septicemic shock who was the victim who survived for 21 days after sustaining gun-shot injuries.

The commonest targeted body parts were the peripheries including the upper and lower limbs (33.04%). The next to follow was the chest in 36 cases (31.30%). Abdomen including pelvis was targeted in 18.26% cases and head was the soft target in only 14.78% cases. Lease affected body part was neck with only 3 cases.

The anatomical locations of fatal gunshot injuries were determined in all 11 cases.

The head (54.55%) was the most common site of fatal gun-shot injuries followed by chest (36.36%). In 9.09% cases the fatal gunshot was an abdominal region and resulted in death due to haemorrhagic shock. A single case of head injury died due to septicemic shock. All cases of fire arm injuries on the chest region also died due to shock and haemorrhagic.

Table 4: Distribution of Victims of Firearm Injuries according to the targeted body part in gun-shot injuries and range of fire

N=115

Body Parts	Range of fire					Total	Percentage
	Distant	Undetermined	Contact	Close	Near		
Periphery	22	12	02	02	00	38	33.04
Chest	15	19	01	00	01	36	31.30
Abdomen	11	09	00	01	00	21	18.26
Head	11	01	05	00	00	17	14.78
Neck	01	01	00	01	00	03	2.61
Total	**60**	**42**	**08**	**04**	**01**	**115**	**100**

Entry wounds were analyzed on the basis of their characteristics appearance to naked eyes, presence of blackening. Scorching, tattooing and singeing were in cases of close range fire at the same time presence of inverted margins, abrasion and contusion collar etc. in distant range fire.

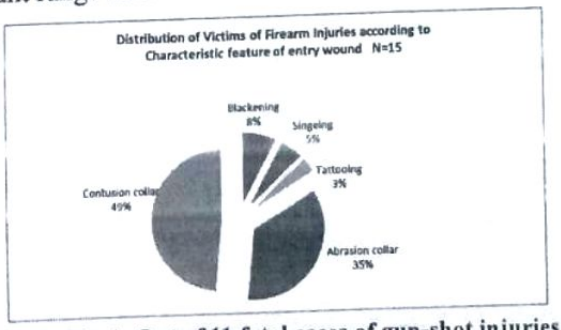

FIGURE NO. 1: Out of 11 fatal cases of gun-shot injuries, brain was the most commonly affected vital organ (54.55%) followed by heart (18.18%), liver & Intestine in one case each.

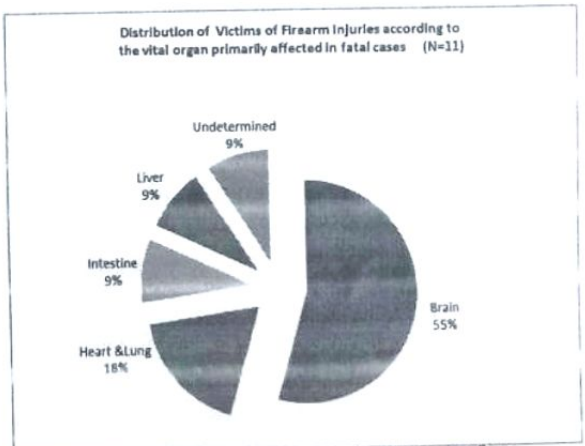

FIGURE 2. In a single case of gunshot injury of an unidentified individual whose dead body was recovered as partially skeletonised being in the advanced stage of putrefaction, foreign bodies were recovered from both skull and thoracic cage due to which the vital organ primarily affected could not be assessed definitely.

DISCUSSION

Out of 115 victims of firearm injuries, only 9.57% people suffered fatal injuries. Most of the other authors have studied only fatal firearm injuries. Among the fatal cases, 05 (45.45%) died within 6 hours including 3 spot deaths; 02 (18.18%) in next eighteen hours i.e. in 6-24 hours after the injury. Rest 04 patients (36.36%) victims survived the event for more than one day. Sachan R et al Kanpur 2013 [3] reported similar results.

Homicides (78.26%) were the most common manner of firearm injuries in the present study followed by 19 (16.52%) accidental and 02 (1.74%) suicidal firearm injuries.

Homicidal intent was predominant in most other studies like of Sachan R et al Kanpur 2013 (92%) [3], Chaurasia N Varanasi 2014 (85.4%)[4], Patnaik K K et al Behrampur 2014 (96%)[5], Kumari S et al Agra 2014 (88.34%).[6] Other studies have considered either only homicidal like of Patowary AJ et al Guwahati 2005[7], Pradipkumar KH et al Imphal 2005[8] or suicidal firearm injuries by Rao D Bangalore 2015[9]. The preponderance of homicide in gun-shot injuries is explainable as these deadly weapons are generally used in planned manner or more so impulsively in a planned assault.

Rifled firearm weapons (72.17%) were the most commonly employed firearm weapon to offend the victims in the present study followed by smooth bore fire arm weapon (27.83). But, our results are not in accordance with those of Kumari S et al Agra 2014.[6]

Distant fires (52.17%) were the predominant offending shot in the present study similar to that reported by Pradipkumar KH et al Imphal 2005.[8] In 36.52% cases the range remained undetermined due to lack of the characteristic features of firearm wounds. Close (3.48%) and contact (6.96%) range fires were found in less numbers, which is quite obvious owing to the lesser representation of suicidal gun-shot injuries in this study. distant fires had produced most fatal wounds in this study, followed by contact shots. But our findings were quite low in comparison to those of Kumari S et al Agra 2014 (53.3%)[6] and Sachan R et al Kanpur, 2013 (60.66%). [3]

There was presence of entry wounds in all 100% victims. In 52.04% cases there was a single entry wound as also reported by Patowary AJ Guwahati 2005[7] which was quite low from that of Kumari S et al Agra 2014 (95% with only 5% cases of double firing)[6] but findings of the present study were quite low in comparison to other studies done in the same state, Kumar R, Varanasi 2013[10] and Sachan R et al. Kanpur 2013[3]. This is explainable as the majority of the gun-shot wounds in this study were distant fires. In the present study, a single exit wound was found in 16.52% cases and in 1.74% cases there were two exit wounds. These results are quite low in comparison to those of Kumar R Varanasi 2013[10] and Kumari S et al Agra 2014 [6] who reported presence of exit wounds in 61.36% (with one exit wound in 18.18%, two in 19.31%, three in 10.22% and more than three exit wounds in 13.63% victims) & 60% victims (with single exit wound in 86.7% and double exit wounds in 13.3% cases) respectively. Abrasion and contusion collars were the most consistent findings in entry wounds of rifled firearm weapons. The characteristic features of blackening, singeing and tattooing were seen in relatively fewer number of entry wounds, because the majority of gun-shot entry wounds in this study were distant fires. Blackening was seen in 12 cases and tattooing were in 5 cases. These findings of the present study are very low from those of Kumar R Varanasi 2013[10] and Kumari S et al Agra 2014 [6] and can be attributed to the variation in the predominantly used firearm weapon and range of fire in both studies.

Chest (31.3%) remained the most commonly targeted body region in this study followed by abdominal region (18.26%) and, head & face (14.78%). These results bear slight variation with those of Kumari S et al Agra 2014 [6](most common site was abdomen- 30.9%, followed by chest- 21% and head- 16%). In 33.04% cases firearm wounds were found on peripheries and neck was the least affected part of the body (2.61%) and those of Sachan R et al Kanpur 2013 [3] where abdomen followed by head & neck was the commonest site.

In fatal cases of firearm injuries, head (54.55%) was the most commonly targeted body part followed by chest (36.36%) and abdomen (9.09%); similar to observations of Pradipkumar KH et al Imphal 2005.[8] Head region also remained the target in both cases of suicidal deaths being the most vulnerable site for suicide with firearm weapon. But, these are variable from those of Kumar R Varanasi 2013[10] and Patowary AJ Guwahati 2005 [7] where chest followed by neck and head and Patnaik K K et al Behrampur 2014 [5] where chest followed by head were the most commonly offended body parts in

fatal cases with 25% fatal entry wounds in abdomino-pelvic region too. In the present study, peripheries and neck were not affected in fatal gun-shot injuries as also reported by Patnaik K K et al Behrampur 2014[5] who reported only 7% firearm wounds in lower limbs in fatal cases.

Brain and meninges (54.55%) were the most commonly injured vital organ in fatal cases followed by lung& heart (18.18%); similar to that reported by Kumar R Varanasi 2013.[10] However, this was not so in the observations of Patnaik K K et al Behrampur 2014 [5]who reported highest involvement of lungs (29%) followed brain, stomach and intestine (16% each). Liver and intestines were the least affected internal organs in this study (9.09% each); which is again quite low as that reported by Patnaik K K et al Behrampur 2014[5] but the differences are easily attributable to the differences of the pattern of gun-shot injuries sustained by victims in the two studies. No other vital structures were observed to be affected in fatal cases of gun-shot injuries.

In 90.43% cases, gun-shot injuries was the only injury sustained on the body and in rest 9.57% cases; associated injuries of blunt trauma were seen on the body possibly due to struggle or secondary impacts after firearm injuries, but these were not fatal. The findings are similar to those of Kumar R Varanasi 2013[10] who reported the presence of associated injuries in 8.33% victims suffering fatal injuries; but quite high from those reported by Pradipkumar KH et al Imphal 2005 (2.99%).[8] Foreign body was recovered from the body in 34.78% cases. Wound debridement was the most commonly employed treatment modality, possibly due to preponderance of distant fires on peripheral parts of the body. Exploratory laparotomy, chest tube drainage and craniotomy were the other treatment modalities employed in different patients according to the type and site of gun-shot wounds suffered.

Coma due to head injury and Shock & hemorrhage resulting from gunshot injuries (45.45% each) were the cause of death in most fatal cases. Only one case (9.09%) died due to septicemia consequent to firearm injury. Hemorrhagic shock was the most common cause of death in the study of Patowary AJ Guwahati 2005[7], Kumari S et al Agra 2014[6] and Sachan R et al Kanpur 2013.[3]

CONCLUSSION

- Rifled firearm weapons (72.17%) were the most commonly employed firearm weapon to offend the victims in the present study followed by smooth bored weapon in 27.83%.
- Distant fires (52.17%) were the predominant offending shot in the present study.
- In 52.04% cases there was a single entry wound. More than one fire was found in 19.13% cases in the present study. Exit wounds were present in only 18.26% cases.
- In 73.04% cases, only a single body region was inflicted upon by use of firearm weapon.
- Coma due to head injury and Shock & hemorrhage resulting from gunshot injuries (45.45% each) were the cause of death in most fatal cases.

Ethical Clearance: Ethical clearance for the study was obtained from Institute Ethics Committee of SMS Medical College, and attached group of Hospitals, Jaipur.

ABSTRACT

BACKGROUND: Firearm injury is a global problem and causes considerable problems in a developing country like ours, where poverty and violence are common. **AIMS AND OBJECTIVE:** To assess the load and analyze the cases of firearm injuries and associated deaths reported at the Department of Forensic Medicine, SMS Medical College & Hospital, Jaipur. **MATERIAL & METHODOLOGY:** The present prospective study had been conducted in the Department of Forensic Medicine & Toxicology, Govt. SMS Medical College & Hospital, Jaipur during the period from May 2014 to October, 2015. **RESULT & OBSERVATION:** In our study majority of case [44 cases (38.26%)] were observed in the age group of 20-29 years. Majority of victims [102 cases (88.70 %)] belongs to rural area. Out of 115 cases of firearm injuries victim 79.13% were literate and 24 cases (20.87%) were illiterate. Property disputes were the most common motive in our study (42.61%) followed by revenge (13.91%), robbery (12.17%). Agriculture was the most common occupation of victims of gun-shot injuries (31.30%) followed by self employed (19.13%).80% victims were found to be married and rest 20% were unmarried. **CONCLUSION:** Educational efforts, and individual, community and societal approaches are needed to alleviate firearm related injuries.

Key Word: Firearm injury, Gunshot, Prospective study, Jaipur

INTRODUCTION

Firearm injury is a global problem and causes considerable problems in a developing country like ours, where poverty and violence are common. Firearms have been used, and continue to be used, both for homicidal and suicidal purposes, offering an easy and quick mode of injury or death. Intimately related to firearm use is the availability of firearm weapons of various types to the public in most parts of the world.[1] Firearms provide a means whereby a person can be killed without any physical contact between the victim and the assailant and provide an opportunity for escape by the offender and therefore, are becoming a weapon of choice. Firearm death is one of the important indicators of level of social and mental health. Firearm injuries have a serious psychological and social impact on the family and community. Pattern of firearm injuries is a reflection of the prevailing social set up and mental status of the region.[2] Data on firearm injury in a particular geographic area can also give the reflection of its law and order situation. A low value can be described in favour of peace, harmony and security to human life.

AIMS & OBJECTIVES

To assessment of socio-demographic profile of victims of firearm injuries reported at the Department of Forensic Medicine, SMS Hospital, Jaipur during the study period from May, 2014 to October, 2015.

- To study the medico-legal profile of firearm injuries.
- To suggest recommendations for preventing fire arm injuries so precious human life can be saved.

MATERIALS & METHOD

All the cases of firearm injuries, irrespective of age, gender and socioeconomic status received at the

casualty of SMS Hospital, Jaipur, dead or alive, later admitted to various wards of SMS Hospital, Jaipur were included in the study during the period from May 2014 to 31st Oct 2015. Hence, 115 cases of firearm injuries reported at the Department of Forensic Medicine, SMS Hospital, Jaipur were analyzed to find out the load of firearm injuries. The personal details pertaining to socio-demographic profile were recorded in detail followed by physical examination.

OBSERVATIONS & RESULTS

Out of 115 cases, majority of the cases were in the age group of 20-29 years (38.26%) followed by age group of 30-39 years (28.70%) which comprised about 66.96% of total cases. The least affected age groups with only 2 cases each were < 10 years and > 60 years. The males were the predominantly affected sex comprising of 89.57% cases with only 12 females among these 115 cases and male: female ratio in this study was 8.58:1.

Table 1: Age and Sex Wise Distribution of 115 Victims of Firearm Injuries

Age group (in yrs)	No. of Males Victims	No. of Females Victims	Total No. of Victims	Percentage of Victims
<10	01	01	02	1.74
10-19	08	01	09	7.83
20-29	42	02	44	38.26
30-39	28	05	33	28.70
40-49	13	01	14	12.17
50-59	09	02	11	9.57
>60	02	00	02	1.74
Total	103 (89.57%)	12 (10.43%)	115	100

There was a rural preponderance (88.70%) in the victims of firearm injuries. 11.30% victims were from urban regions.

Table 2: Distribution of 115 Victims of Firearm Injuries according to Domiciliary Status

Domicile	No. of cases	Percentage
Rural	102	88.70
Urban	13	11.30
Grand Total	115	100

Out of 115 cases of firearm injuries victim 79.13% were literate and 24 cases (20.87%) were illiterate. It was proposed to gather information of the educational status of victims to correlate it to judicious and non judicious use of firearms according to level of education.

Table 3: Distribution of 115 Victims of Firearm Injuries according to literacy Status

Literacy Status	Number of Cases	Percentage
Literate	91	79.13
Illiterate	24	20.87
Grand Total	115	100

Motive of victim were identified by detailed history by relatives and eyewitness. Property disputes were the most common motive behind the incidence (42.61%) followed by revenge 13.91%), robbery (12.17%) and group quarrel (06.96%). In 10.43% cases the motive behind the incidence remained undetermined. The least common motive behind gun-shot injuries in this study was love affairs and defensive actions (02.61% each). [Table No. 4]

Table 4: Distribution of 115 Victims of Firearm Injuries according to the Motive behind the gun-shot injuries

Motive behind GSI	Number of cases	Percentage
Property disputes	49	42.61
Revenge	16	13.91
Robbery	14	12.17
Unknown	12	10.43
Accidental (no motive)	10	08.70
Group Quarrel	08	06.96
Love Affair	03	02.61
Defence	03	02.61
Grand Total	115	100

Agriculture was the most common occupation of victims of gun-shot injuries (31.30%) followed by self employed (19.13%), people in jobs and students (17.39% each). A handful of property dealers (5.22%) were also victims of gun-shot injuries. 7.83% victims were housewives which comprised 75% of total females. Ex-serviceman was 0.87% of victims. [Table No. 5]

Table 5: Distribution of 115 Victim of Firearm Injuries according to Occupational Status.

Occupational Status	Number of cases	Percentage
Agriculture	36	31.30
Self Employed	22	19.13
Service	20	17.39
Student	20	17.39
Housewives	09	07.83
Property	06	05.22
Ex servicemen	01	00.87
Not applicable	01	00.87
Grand Total	115	100

Marital status of victims was recorded among studied cases and 80% victims were found to be married and rest 20% were unmarried. Married men and women were more commonly affected with gun-shot injuries. [Table No. 6]

Table 6: Distribution of 115 Victim of Fire Arm Injuries cases According to Marital Status and Sex.

Marital Status	No. of Male	No. of Female	Total No. of cases	Percentage
Married	82	10	92	80.00
Unmarried	21	02	23	20.00
Total	103 (89.57%)	12 (10.43%)	115	100

Maximum incidences took place in village in accordance with the rural preponderance of victims. A major handful of them took place at home with least numbers occurring at workplace and in school. In 1 case the place remained undetermined as the dead body for shifted from scene of crime for concealment of the incidence, probably of homicidal intent. 66.95% incidences of firearm injuries occurred in outdoor settings whereas 32.18% incidences occurred in indoor settings.

Table 7: Distribution of 115 Victims of Firearm Injuries according to the place of incidence.

Incidence Place	Number of Cases	Percentage
Village	47	40.87
Home	30	26.09
Farm	11	9.57
City & Streets	10	8.70
State highways	09	7.83
Work place	06	5.22
School	01	0.87
Unknown	01	0.87
Grand Total	**115**	100

DISCUSSION

Maximum numbers of cases were from 20-39 years of age (66.96%) with peak incidence in 20-29 years (38.26%) which are the productive and active members of the society. The observations of the present study were similar to those of **Patowary AJ et al[3] ; Pradipkumar KH et al[4]; Sachan R et al[5] ; Kumar K et al[6] and Chaurasia N et al[7]** (peak incidence between 21-40 years of age in all). However, the results of the present study are variable from those of **Kumari S et al[8]** who reported maximum number of cases in 11-20 years followed by 21-30 years. The probable reason for this variation is the minor cultural and periodical differences as most other studies from the same state also report the highest incidences of such cases between 21-40 years. [Table No. 1] Males (89.57%) outnumbered the females (10.43%) in the present study with a male: female ratio of about 8.58:1 .Similar results have been reported by **Patowary AJ et al[3]**, (88.9% males); and, **Kumari S et al[8]** (90% males). Males are the active participants of the society and more commonly engaged in outdoor activities. Moreover, they are more prone to episodes of rage and revenge. This explains the male preponderance in all studies. [Table No. 1] The victims of firearm injuries in this study showed a rural preponderance (88.70%) with only 11.30% victims from urban population. **Chaurasia N et al[7]** also showed preponderance of rural victims with slight variations in proportions of the two (72.9& rural & 27.1% urban victims) in both studies. This is probably due to the easy availability of illegal firearms in rural regions owing to easier violation of laws. It is difficult to implement strict laws in rural areas for many reasons, like, large area, lower literacy rates, cultural influences, socio-political constraints etc. [Table No. 2] 79.13% victims in the present study were literate in the present study and 20.87% were illiterate. Although there was a rural preponderance in the study population yet the literacy status of the study population was high. It is expected from educated people to use such deadly weapons judiciously. However the literacy rates are not an indicator of the level of education. Educational status has not been described as a variable in most studies. [Table No. 3] Land and property disputes were the most common reason behind firearm injuries in this study (42.61%) followed by revenge & robbery (13.91% & 12.17% respectively); group quarrel accounted for another 6.96% cases. The results of the present study are quite similar to those of **Sachan R et al[5]** , who reported 29.51% gun-shot injuries due to property disputes; 21.1% for dacoity; 13.11% for personal enmity & 22.95% in group quarrel. But, in slight variation to those of **Chaurasia N et al[7]** and, **Kumar K et al[6]**, where maximum homicides occurred for personal enmity (58.3% & 51% respectively). Considering the occupational status of the victims, it was observed that agriculture was the most common occupation among victims (31.30%), which is quite obvious owing to the preponderance of rural population in

this study. 19.13% victims were self employed. In all, 81.74% victims were from non service sector including agriculture, business (24.35%), students (17.39%). 75% of females were housewives (7.83% of all cases). Occupation of one victim was unknown. The higher numbers of persons from agricultural field is also attributable to the fact that land is an important cause of disputes leading to such heinous crimes either in impulse or with planning. The business sector also included property dealers who comprised 5.22% of the total population. Our results are quite similar with slight variations to those of **Chaurasia N et al**[7] (90.6% victims from non service sector). [Table No. 5] About 80% victims of both sexes were married in the present study. It bears no correlation with such incidences but any type of outrageous behavior is more common after marriage due to the burden of responsibilities that come hand in hand with it. Data pertaining to marital status is not descriptive in most other studies but is quite evident by the majorly affected age ranges in those studies. [Table No. 6] The overall incidences in outdoor scenes were 66.95%. Home (26.09%) was the preferred incidence place, possibly in planned homicides for personal enmity and revenge, where the victim was attacked when relaxed in home. A total of 32.18 % cases occurred in indoor settings like home, school and work place. Our results are in accordance with those of **Kumar K et al**[6]. The place of incidence remained unknown in a single case. Among the two suicidal cases, one occurred at home of victim and the other at workplace.

CONCLUSION

The results of the present study support the argument that rigorous pursuit of campaign firearms without a license and country made guns may prove useful in reducing the number of firearm injuries in society. Following efforts, and individual, community and societal approaches are needed to alleviate firearm related injuries.

- Proper employment facility for the youth.
- Social stability and creation of proper political environment
- Strong and effective measures to control the unlicensed arms.
- Private gun ownership should be strictly limited.
- The issue of medical certificates for acquiring license of fire arms should be strictly monitored for psychiatric assessment.
- There should be proper training of maintenance, cleaning & handling of fire arm weapons at the time of sale to minimize accidental gunshot injuries.

Load of Firearm Cases in Male at SMS Medical College, Jaipur

Shanti Lal Pargi[1], Lovekumar Bhagora[2], Deepali Pathak[3], R.K. Punia[4], Rohit Kumar Meena[5]

[1]Assistant Professor, Dept. of Forensic Medicine, Ananta Institute of Medical Science & Research Center, Rajsamand, Udaipur, [2]Assistant Professor, Dept. of Forensic Medicine, Geetanjali Medical College, Udaipur, [3]Associate Professor, Dept. of Forensic Medicine, SMS Medical College, Jaipur, [4]Professor, Dept. of Forensic Medicine, SMS Medical College, Jaipur, [5]Senior Resident, Dept. of Forensic Medicine, SMS Medical College, Jaipur, Rajasthan

Abstract

Introduction: A Firearm is a thermodynamic machine in which the potential energy of the gun- powder is transformed into the kinetic energy of the projectile.

Aims and Objective: To assess the load and analyze the male cases of firearm injuries.

Material and Methodology: The present prospective study had been conducted in the Department of Forensic Medicine, SMS Medical College & Hospital, Jaipur, Rajasthan during the period of One & half year from May 2014 to October 2015. All cases of firearm injuries that were received dead or live at SMS Hospital and its attached Hospitals, Jaipur was included in our study.

Result and Observation: In our study majority of firearm injury case [43 cases (40.78%)] were observed in the age group of 20-29 years followed by the age group of 30-39 years [28 cases (27.18%)]. Majority of the incidences of gun-shot injuries were homicidal in nature (80.58%) followed by accidental episodes (14.56%). Land and property disputes were the most common reason behind firearm injuries in this study (42.72%) followed by revenge & robbery (15.53% & 13.59 % respectively);Majority of the incidences occurred during evening in 43 cases (41.75%), followed by afternoon 40 cases (38.83%). There was presence of firearm entry wound in all victims. Overall,52 cases (50.49%) had a single entrance wound, 13 cases(12.62%) had two entry wounds, In summer season 43 cases (41.75%), spring 24 cases (23.30%), winter 20 cases (19.42%), autumn 16 cases (15.53%), were reported in studied cases. In majority of the cases (81.55%), there was no exit wounds while one exit wound was found in 17 cases (16.51%).In rest of the two cases, two exit were found in two cases.

Conclusion: The results of the present study support the argument that rigorous pursuit of campaign firearms without a license and country made guns may prove useful in reducing the number of firearm injuries in society.

Introduction

A Firearm is a thermodynamic machine in which the potential energy of the gun- powder is transformed into the kinetic energy of the projectile[1].

Firearms and explosives constitute convenient means of destroying human life from considerable distance, providing opportunity to the offender to escape;

it has been the weapon of choice for gangsters, terrorists, extremists, antisocial and anti-national elements for eliminating their victims. Its use is increasing in recent years because of easy availability due to manufacture of huge amount of arms, ammunition and explosives and free snuggling across the international borders[2].

Data on firearm injury in a particular geographic area can also give the reflection of its law and order situation. A low value can be described in favour of peace, harmony and security to human life[3].

There is growing concern about the indiscriminate use of firearms on a large scale, particularly in the last decade. The availability of firearms known as small arms and light weapons (SALW) has been described as a cancer spreading across the developing world[4].

This study was thus undertaken to assess the load of gun-shot injuries among in Jaipur region and to ascertain the medico-legal and socio-demographic profile of cases presented at SMS Medical College, Jaipur during the study period along with associated deaths in Jaipur region to look for reason behind them; and also to suggest few recommendations which may prove useful in bringing down the toll of firearm injuries in this region.

Aims and Objectives: To assess the load and analyze the cases of firearm injuries and associated deaths reported at the Department of Forensic Medicine, SMS Hospital, Jaipur during the study period (May, 2014 to October, 2015).

To study the load of firearm injuries and associated deaths reported at the Department of Forensic Medicine during the study period .

To study the medico-legal profile of firearm injuries.

To study the socio-demographic profile of victims of firearm injuries.

Material and Methodology

All the cases of firearm injuries, irrespective of age, gender and socioeconomic status received at the casualty of SMS Hospital, Jaipur, dead or alive, later admitted to various wards of SMS Hospital, Jaipur were included in the study. All cases of firearm injuries that were received dead at SMS Hospital and its attached Hospitals, Jaipur was autopsied at the mortuary of SMS Hospital, Jaipur and included in the study. Also the cases of non fatal firearm injuries admitted to various wards of SMS Hospital and its attached hospitals, Jaipur were included in the study after receiving an informed consent for the same. All the observations were recorded in the pre proposed Performa as detailed above. The results of the present study were further compared to other contemporary studies from various parts of the country.

Observations and Result

Table 1: Age and Sex Wise Distribution of Firearm Injuries Cases.

Age group (in yrs)	Total no. of cases	Percentage (%)
<10	01	0.97
10-19	08	7.77
20-29	42	40.78
30-39	28	27.18
40-49	13	12.62
50-59	09	8.74
>60	02	1.94
Total	**103**	**100**

Out of 103 cases, majority of the cases were in the age group of 20-49 years [(42 cases (80.58%)] which is productive age group of society. Among these, maximum cases were in the age group of 20-29 years which comprised about 40.78% of total cases. The other age groups affected in descending order were the 4th, 5th, 6th and 2nd decades. The least affected age groups with only 2 cases and 1 case below 10 years and above 60 years respectively.

Table 2: Manner Wise Distribution of Firearm Injuries Cases.

Manner	Total no. of cases	Percentage (%)
No. of Homicidal case	83	80.58
No. of Accidental case	15	14.56
Unknown cases	3	2.91
No. of Suicidal case	2	1.94
Total no. of cases	**103**	**100**

Homicides (80.58%) were the most common manner of firearm injuries in the present study followed by 15 cases (14.56%) accidental and 02 cases(1.94%) suicidal firearm injuries. The manner remained undetermined in 03 cases (2.91%).

Table 3: Motive Behind the Incidence Wise Distribution of Firearm Injuries Cases.

Motive behind incidence	Total no. of cases	Percentage (%)
Property disputes	44	42.72
Revenge	16	15.53
Robbery	14	13.59
Unknown	09	8.74
Accidental (no motive)	09	8.74
Group Quarrel	05	4.85
Love Affair	03	2.91
Defence	03	2.91
Grand Total	**103**	**100**

Land and property disputes were the most common reason behind firearm injuries in this study (42.72%) followed by revenge & robbery (15.53% & 13.59 % respectively); group quarrel accounted for another 5 cases(4.85%) and there were 03 cases each (2.91%) for defense and love matters/sexual jealousy. In 9 cases (8.74%), the motive remained undetermined.

Table 4: Time of Incidence Wise Distribution of Firearm Injuries Cases.

Day of Incidence	Total no. of cases	Percentage (%)
Evening	43	41.75
Afternoon	40	38.83
Morning	9	8.74
Night	10	9.71
Unknown	01	0.97
Total	**103**	**100**

Majority of the incidences occurred during evening in 43 cases (41.75%), followed by afternoon 40 cases (38.83%), night 10 cases (9.71%) & morning 9 cases (8.74%) The time of incidence remained undetermined in a single case (0.97%).

Table 5: Season of Incidence Wise Distribution of Firearm Injuries Cases.

Season of incidence	Total no. of cases	Percentage (%)
Summer	43	41.75
Spring	24	23.30
Winter	20	19.42
Autumn	16	15.53
Total	**103**	**100**

In summer season 43 cases (41.75%), spring 24 cases (23.30%), winter 20 cases(19.42%), autumn 16cases (15.53%), were reported in studied cases. Maximum were in summer and least in autumn.

Table 6: Number of Exit Wounds in Gun-Shot Injuries Wise Distribution of Firearm Injuries Cases.

Number of Exit wounds	Total no. of cases	Percentage (%)
None	84	81.55
One	17	16.51
Two	02	1.94
Total	**103**	**100**

In majority of the cases [84 cases (81.55%)], there were no exit wounds while one exit wound was found in 17 cases (16.51%).In rest of the two cases, two exit wound were found in two cases.

Discussion

Maximum numbers of cases were from 20-39 years of age (67.96%) with peak incidence in 20-29 years (40.78%) which are the productive and active members of the society. The observations of the present study were similar to those of **Patowary AJ et al[4], Sachan R et al[5], Kumar K et al[6]** (peak incidence between 21-40 years of age in all). However, the results of the present study are variable from those of **Kumari S et al[7]** who reported maximum number of cases in 11-20 years followed by 21-30 years. The probable reason for this variation is the minor cultural and periodical differences as most other studies from the same state also report the highest incidences of such cases between 21-40 years.

Homicides [83 cases (80.58%)] were the most common manner of firearm injuries in the present study followed by 15 cases (14.56%) accidental and 02 cases (1.94%) suicidal firearm injuries. The manner remained undetermined in 03 cases (2.91%). Homicidal intent was predominant in most other studies **Sachan R et al[5], Kumar K et al[6] and Kumari S et al[7].** Other studies have considered either only homicidal **Patowary AJ et al[4]**or suicidal firearm injuries. The preponderance of homicide in gun-shot injuries is explainable as these deadly weapons are generally used in planned manner or more so impulsively in a planned assault. It is not very easy to procure such weapons and not that very easy to carry it due to legal restraints, so, they are not

the weapon of choice in fights and assaults. They are mostly used in planned episodes of homicidal or suicidal injuries. Accidental injuries with firearms are also not uncommon as users are prone to such episodes while cleaning, maintenance or erratic handling of loaded guns. Accidental injuries were seen in this study in 16.52% cases but these results are quite high as compared to studies of **Kumar K et al[6] and Kumari S et al[7]**.

Land and property disputes were the most common reason behind firearm injuries in this study [44 cases (42.72%)]followed by revenge 16 cases(15.53%) & robbery 14 cases (13.59 %); group quarrel accounted for another 5 cases (4.85%) and there were 03 cases each (2.91%) for defense and love matters/sexual jealousy. In 9 cases (8.74%), the motive remained undetermined. As per **Kumar K et al[6]** the motive remained undetermined in a single case of accidental firing (1.73%). This difference is attributable to the variation in the proportion of accidental incidences in the two studies. There were 10 cases of purely accidental gun-shot injuries where motive was lacking. According to **Patowary AJ et al[5] .** Most cases were due to militant activities, encounters, riots, robberies or family quarrel. This variation from our study is due to the regional variations in the areas of study as Guwahati and Imphal are militant activity prone areas. The results of the present study are quite similar to those of **Sachan R et al[5]**. But, in slight variation with **Kumar K et al[6]** where maximum homicides occurred for personal enmity. The motives behind the homicidal attack with firearm weapons were well represented in different cases with property land disputes majorly responsible followed by personal enmity and robbery.

Most of the events of firearm injuries occurred during evening hours (41.75%) followed by afternoon (38.83%). These are the hours of work and business, thus prone to activity during which the untoward event took place. 8.74% incidences took place in morning hours. Thus, it was observed that in 47.57% cases, the incidence took place in broad daylight and 52.43% cases occurred after sunset; as also reported by **Kumar K et al[6].** The late night hours witnessed the least numbers of gun-shot injuries (8.7%) in the present study which is in contrast to the findings of **Kumari S et al**. The suicides (two cases) were committed in morning and evening each.

None of the season was poorly represented by episodes of firearm injuries and deaths. However, summer season was most flooded with events of firearm injuries in the present study (41.75%) followed by spring (23.30%) and winter (19.42%). This is quite explainable as maximum events in this study took place for land disputes in villages. Summer season is a comparatively relaxing one for those engaged in Agriculture as the main crop of this region is through by the end of spring. After the harvest of the crop, the disputes probably come to surface owing to distribution of revenue generated.

Exit wounds were present in only 84 cases (18.26%) i.e. in majority of the victims, firearm exit wounds were not present. These are quite less in number due to the predominance of distant fires in this study. In the present study, a single exit wound was found in 17 cases (16.51%) and in 2 cases (1.74%) there were two exit wounds. These results are quite low in comparison to those of **Kumar R et al[2]** and, **Kumari S et al[7]** who reported presence of exit wounds in 61.36% & 60% victims respectively.

Conclusion

This study indicated that the most common victims of firearm injuries were young males of bread earning age followed by youth which raises concern towards this issue. Certain changes may minimize mortality and disability due to firearm injuries, also reducing the costs to the community. As a result of the invention of more advanced firearms and availability at the global level, death rates due to firearm injuries have increased recently. There is a powerful correlation between acquisition of a firearm and its use in murders, suicides and unintentional deaths. So, there is a need to decrease the number of firearms used and sold in India.

The results of the present study support the argument that rigorous pursuit of campaign firearms without a license and country made guns may prove useful in reducing the number of firearm injuries in society. Educational efforts and individual, community and societal approaches are needed to alleviate firearm related injuries.

Delay in treatment proves fatal

By Radhika D Srivastava
Times News Network

NEW DELHI: Hindu Rao Hospital which is equipped with a non-functional CT scan machine and no neurosurgeons, kept a road accident victim with a head injury for 15 hours before referring him to a specialised hospital.

The delay proved to be fatal as the victim could have been easily saved otherwise.

Jasbir Singh, 23, met with an accident near Wazirpur on September 12 around 7.30 pm. He was apparently riding a two-wheeler which was hit by a heavy vehicle.

Brought to Hindu Rao Hospital around 8.30 pm, doctors found his pupils dilated and that he was not responding to "painful stimulus." Singh quite clearly had head injuries.

He was admitted and administered decongestant drugs. His condition was described as "extra-dural haematoma", a situation when blood collects between the brain's outermost protective membrane and the skull.

A doctor explained, "Just a simple, small hole — known as a Burr Hole — could have been made in the skull and the blood drained out."

All through the night Singh bled inside the head. The hospital's CT scan machine had not been functioning for the past two years, but Singh was not referred to another hospital.

The next morning, September 13, Singh's condition had visibly deteriorated, and his family was told to take him to Sushrut Trauma Centre on Ring Road.

Neurosurgeons at the centre were appalled by the delay. A doctor said, "If a hospital does not have a CT scan machine it has no business to keep a head injury patient for over 15 hours."

Within hours Singh was operated on. He remained in intensive care for four days and died on September 17.

Hindu Rao hospital's chief medical officer Dr A K Pasrecha said, "When Singh was brought to us he appeared to be under the influence of alcohol. The doctor on duty did not see any sign of head injury."

Dr Pasrecha added, "The next morning when the alcohol influence reduced, we suspected a head injury and referred him to Sushrut Trauma Centre." The case history from Hindu Rao sent along with Singh made no mention of alcohol.

KEY FEATURES

- Contains colour photographs of more than 160 poisons.
- The book aims to provide to the students of MBBS, Ayurveda & Homeopathy proper preparation for theory and practical examinations.
- The language is simple and easily understandable.
- Designed for easy retention of difficult concepts.
- Contains information and practical hints for the practitioners.

Expert Opinions :

- **Dr. V. K. JAYAPALAN**
  (Ex-president, IAFM & Ex - DMER, Kerala)
  The book is in simple language, lucid style & easy presentation.
- **Dr. B. R. KATE**
  (Ex-DMER, Maharashtra)
  Book documented in easy language & presented in manner which students desire to be of help to them. A book to be opened with expectation & closed with profit.
- **Dr. N. S. MHASKE**
  (Ex-Secretary, Pravara Medical Trust, Loni)
  The book being in simple language is very useful for all students and practitioners.
- **Dr. P. M. KOLTE**
  (Ex-Dean, D. Y. Patil Medical College, Kolhapur)
  A Master Piece.
- **Dr. R. K. GUPTA**
  (Prof. & H.O.D. of F.M.T. at GMC, Kanpur)
  Excellent book.
- **THOUSANDS OF STUDENTS**
  This book definitely helps us to understand the subject and score better in F.M.T. and pre P. G. entrance examination.

Abstract

Traumatic abdominal wall herniation, especially of the groin region, is a rare condition and typically results from a high-energy trauma to the abdominal wall. We report a fatal case of a road-traffic collision involving a young male motorcyclist who collided with a speeding lorry. The victim sustained multiple injuries over the chest and abdomen, with traumatic inguinal herniation causing gross distension of the scrotum. At autopsy, multiple lacerations of thoracic and abdominal organs were seen, along with traumatic disruption of the right inguinal canal. The contused terminal ileum was present in the scrotal sac. A literature search has revealed a limited number of reported cases of gross inguinal herniation following thoracoabdominal trauma. In cases of high-energy trauma to the thoraco-abdominal region with unilateral or bilateral distension of the scrotum, the possibility of herniation of the abdominal contents into the scrotal sac should be considered by the forensic pathologist.

Keywords

Traffic accident, autopsy, blunt injury, abdominal injury, traumatic inguinal hernia

Introduction

A traumatic abdominal wall hernia (TAWH) is described as a hernia produced due to trauma disrupting the muscles and fascia without penetrating the overlying skin and in the absence of a previous hernia defect at the site of the impact.[1] TAWH was first documented by Selby[2] more than a century ago. TAWH, especially of the inguinal region, is a rare condition in the clinical setting, with a high risk of associated intra-abdominal injuries.[3] The three potentially weak areas of the abdominal wall – the inguinal region, the region lateral to the rectus muscle and the region above the iliac crest in the flank region – are the common sites for TAWH.[4] The inguinal canal lies over medial half of the inguinal ligament and extends from the deep inguinal ring to the superficial inguinal ring. The literature on traumatic cases with gross disruption of the inguinal canal is limited.[5,6] We present a fatal case of traumatic inguinal herniation with complete disruption of all boundaries of the inguinal canal, including deep and superficial rings, causing traumatic herniation of 90 cm of the terminal ileum into the scrotal sac. The reported case highlights an incidental finding of traumatic inguinal hernia, which at times can have serious clinical and medico-legal considerations.

Case report

A 20-year-old male motorcyclist was brought dead to the emergency room with an alleged history of a side-on collision and subsequent run over by a speeding lorry. During autopsy, on external examination, multiple impact and grazed abrasions were present over the chest and abdomen (Figures 1 and 2). Gross distention of the scrotum was evident (Figure 1). Internal examination revealed a fissure fracture of the anterior and middle cranial fossa on the left side, a complete transection of the cervical vertebrae between C5 and C6 and multiple fractures of the sternum, clavicle and ribs bilaterally. Thoracic and abdominal wall examination revealed multiple contusions. All the thoracic and abdominal organs had multiple contusions and lacerations. A significant defect was evident in the lower abdominal wall through which around 90 cm of the

Figure 1. Multiple grazed abrasions over the left side of the trunk and gross distension of the scrotum.

Figure 2. Multiple impact abrasions over the right side of the trunk suggestive of tyre imprint abrasions caused by run over.

terminal ileum was herniating into the scrotal sac (Figures 3 and 4). The cause of death was opined as multiple injuries sustained to the head, neck and trunk. Prior history of inguinal hernia was excluded by asking relatives.

Discussion

The association of blunt trauma to the abdomen and a traumatic inguinal hernia is not infrequently reported in surgical practice. However, traumatic

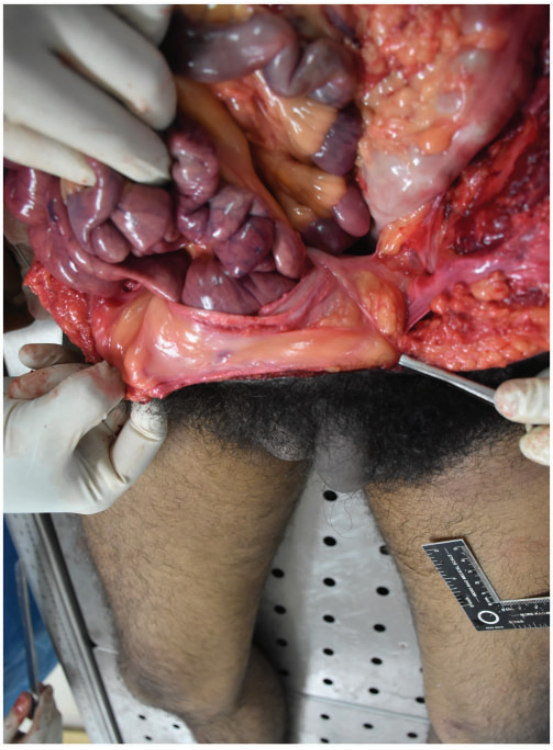

Figure 3. Large defect in the right-sided lower part of the anterior abdominal wall through which the terminal ileum is herniated into the scrotum.

herniation of the intestine remains a rarity in medico-legal autopsies. The most common aetiological factors for traumatic herniation include low-energy trauma such as handlebar injury, bullhorn, sports and seatbelt injuries and high-energy trauma due to road-traffic accidents.[7]

Three types of TAWHs are defined according to the mechanism of injury: type 1 TAWH that describes small hernia in the anterio-inferior abdominal wall and inguinal region caused by low-energy blunt trauma (e.g. handlebar injuries); type 2 TAWH that are large hernia defects caused by high-energy trauma such as road-traffic accidents; and type 3 TAWH that are rare variants seen in acute deceleration injuries.[8]

Blunt trauma to the abdomen can lead to the application of tangential and shearing forces over the abdominal wall, which causes disruption of the abdominal wall muscles and fascia that may result in herniation of the abdominal viscera. As traumatic forces on the abdomen are distributed over a broad area and the skin is more elastic than other layers, the skin usually remains intact.[9] A sudden increase in intra-abdominal pressure along with the shearing effect on the abdominal muscle and fascia is considered the primary aetiological mechanism in the development of traumatic

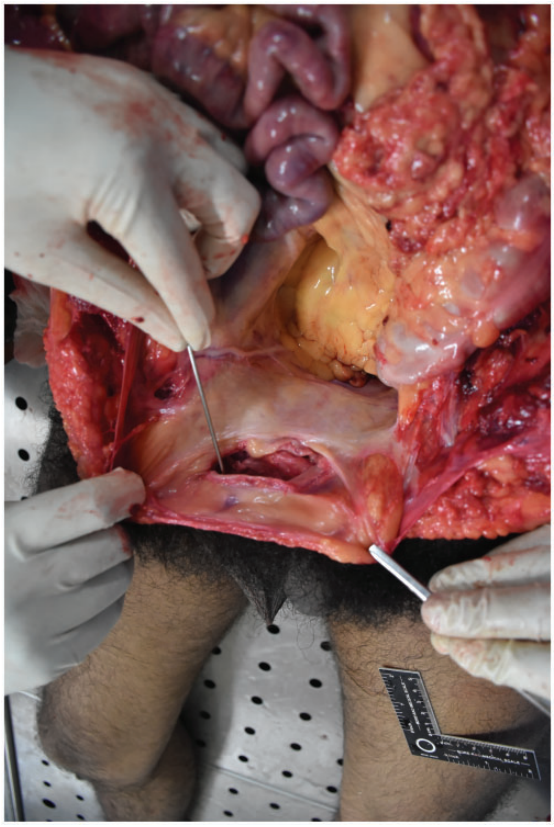

Figure 4. Large defect in the right-sided lower part of the anterior abdominal wall with complete disruption in the inguinal canal, as evident after removal of the terminal ileum that traversed through it into the scrotum. A probe was inserted through it into the scrotum.

hernias. Further, diffuse high-energy impact to the abdomen can cause a large abdominal wall defect, and its association with intra-abdominal injuries is very high. The incidence of intra-abdominal injuries in cases of TAWH is reported in 25–70% of cases.[10]

Netto et al.[3] in their retrospective evaluation of 34 patients with TAWHs, highlighted the mechanism and severity of injuries and made clinical recommendations. First, the mechanism of injury should be taken into consideration in patient management, as high-energy traumas often require urgent exploration. Second, the visible hernia has a high probability of associated intra-abdominal injuries. Third, an occult hernia diagnosed only by radiological means may not require urgent surgical management. Clinically, the appearance of a bulge or tender swelling on the abdominal wall with or without associated skin lesions after an incident of blunt trauma to the abdomen helps establish its traumatic origin, and in doubtful cases, a contrast-enhanced computed tomography scan of the abdomen is considered a valuable tool for early detection of traumatic hernias.[7,11] TAWH in itself can be a primary cause of death. It is recognised that delayed diagnosis of this condition can lead to bowel ischaemia/infarction, whilst it may also be associated with bowel perforation, both of which can prove fatal if untreated.

In cases of high-energy trauma, extra-abdominal injuries such as fractures of vertebrae and the ribs may accompany it.[12] Multiple fractures of the thoracic cage, skull and complete transection of cervical vertebrae were observed in our case which itself signifies the involvement of high-energy crush and shearing forces in the reported case. There is a high possibility of severe intra-abdominal injuries in the case of TAWH following high-energy trauma of the abdomen. Unilateral or bilateral distension of the scrotum following high-velocity trauma to the thoraco-abdominal region should raise a suspicion of TAWH after ruling out scrotal haematoma and emphysema.

Prevalence of microalbuminuria in patients with essential hypertension- A clinical study

Dr. Vipin Goyal

DOI: https://doi.org/10.22271/27069567.2020.v2.i2b.54

Abstract

Background: The present study was conducted to record prevalence of Microalbuminuria in patients with essential hypertension.

Materials & Methods: The present study was conducted on 102 patients of diagnosed essential hypertension of both genders. Microalbuminuria was measured in all patients in a 24h urinary sample.

Results: Out of 102 patients, males were 62 and females were 40. Out of 102 patients, microalbuminuria was present in 40 patients. Maximum cases were seen in age group >70 years (20) followed by 6-70 years (14), 50-60 years (4) and 40-50 years (2).

Conclusion: Authors found the presence of microalbuminuria in a significant number of newly detected and untreated patients of essential hypertension.

Keywords: Essential hypertension, microalbuminuria, coronary heart disease

Introduction

Hypertension is a disorder of circulatory regulation. Sustained hypertension causes accelerated atherosclerosis with consequent coronary heart disease (CHD), heart failure, and stroke and renal failure. If untreated, approximately 50% of patients develop heart disease, 33% develop stroke, and 10%–15% develop renal failure [1].

Hypertension (HT) is a growing public health problem and it is now being widely reported in many rural and urban parts as one of the commonest cause of morbidity and mortality [2]. The reasons for this growing burden are multiple, ranging from socio-economic changes and genetic influence. At a genetic level, there is growing evidence showing an association between elevated diastolic BP and CaMK4 affecting endothelial functions like controlling vascular resistance hence increasing the risk of HT [3].

Microalbuminuria is an early indicator of renal damage and has been demonstrated as one of the principal predictive factors of cardiovascular (CV) complications, all cause and cardiovascular mortality independent of the traditional risk factors like dyslipidemia, hypertension [4]. Left ventricular hypertrophy (LVH) determined either by standard 12-lead electrocardiography (ECG) or echocardiography is also a marker of subclinical organ damage related to hypertension and an independent predictor of cardiovascular morbidity/mortality. Hypertension affects the heart by increasing after load resulting in the left ventricular hypertrophy (LVH) and stiffening of the left ventricle leading ultimately to increase in the left ventricular mass (LVM). LVH is the most common abnormality in patients with hypertension and significant marker of subclinical cardiovascular disease [5].

Screening of all recently diagnosed patients of essential hypertension for microalbuminuria may be a reasonable strategy to predict the presence of ongoing vascular damage, cardiac geometric adaptation, and the future risk for cardiovascular events [6]. The present study was conducted to record prevalence of Microalbuminuria in patients with essential hypertension.

Materials & Methods

The present study was conducted in the department of general medicine. It comprised of 102 patients of diagnosed essential hypertension of both genders. The study was approved from ethical committee. All patients were informed and their consent was obtained.

Demographic profile of the patients was recorded. Patients satisfying inclusion and exclusion criteria were subjected to detailed history and physical examination with special emphasis on the examination of cardiovascular system.

Microalbuminuria was measured in all patients in a 24h urinary sample. Others investigations are blood urea and serum creatinine, plasma glucose – fasting and postprandial, serum electrolytes–sodium and potassium, serum uric acid, serum calcium and phosphate, lipid profile, x-ray chest and electrocardiography. Results thus obtained were statistically analyzed.

Results

Table I: Distribution of patients

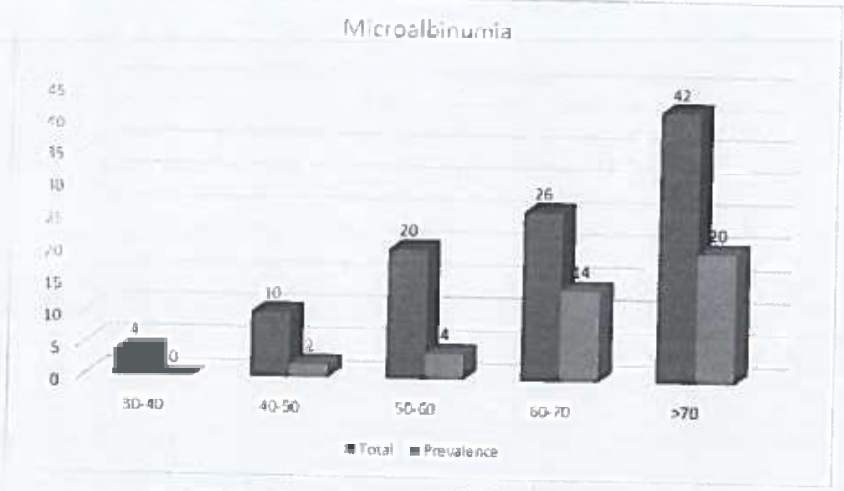
Total- 102		
Gender	Male	Female
Number	62	40

Table I shows that out of 102 patients, males were 62 and females were 40.

Table II: Prevalence of microalbuminuria based on age groups

Age groups (Years)	Total	Prevalence
30-40	4	0
40-50	10	2
50-60	20	4
60-70	26	14
>70	42	20

Table II, graph I shows that out of 102 patients, microalbuminuria was present in 40 patients. Maximum cases were seen in age group >70 years (20) followed by 6-70 years (14), 50-60 years (4) and 40-50 years (2).



Graph I: Prevalence of microalbuminuria based on age groups

Discussion

Hypertension is one of the major public health problems. Worldwide prevalence of hypertension is as much as 1 billion while 7.1 million deaths may be attributable to hypertension [7]. The JNC 7 report states that high blood pressure is the number one attributable risk for death in the world. Uncontrolled hypertension is directly associated with end organ damages including CHD, CHF, LVH, stroke, and peripheral vascular disease. Limited evidence is available among Indian patients regarding significance of microalbuminuria (MA) in context of hypertension and future cardiovascular morbidity [8]. The present study was conducted to record prevalence of Microalbuminuria in patients with essential hypertension.

In present study out of 102 patients, males were 62 and females were 40. Maggon *et al.* [9], determined the prevalence of MA in hypertensive patients and to examine its correlation with severity of hypertension, left ventricular hypertrophy (LVH), and common carotid intima-media thickness (CCIMT). This study demonstrates the presence of MA in a significant number of newly detected and untreated patients of essential hypertension. Further, MA had a statistically significant relationship with LVH and CCIMT. Thus, screening of all recently diagnosed patients of essential hypertension for MA may be a reasonable strategy to predict the presence of future cardiovascular risk. We found that out of 102 patients, microalbuminuria was present in 40 patients. Maximum cases were seen in age group >70 years (20) followed by 6-70 years (14), 50-60 years (4) and 40-50 years (2). Nabbaale *et al.* [10], determined the prevalence of microalbuminuria, LVH in patients with microalbuminuria and the correlation between microalbuminuria and LVH among newly diagnosed black adult hypertensive patients attending a large outpatient hypertension. The mean age/standard deviation of the study participants was 54.3 ± 6.2 years with a female predominance (162, 63.3%). The prevalence of microalbuminuria among newly diagnosed hypertensive patients was 39.5%. The prevalence of LVH among patients with microalbuminuria was found to be 17%. There was a positive correlation between microalbuminuria and left ventricular hypertrophy among the newly diagnosed adult hypertensive patients. This study demonstrates that microalbuminuria is highly prevalent among newly diagnosed black hypertensive patients and in the presence of LVH. There is also a positive correlation between microalbuminuria and LVH among newly diagnosed hypertensive patients. Since it is a less costly and readily available test, it can be used to predict presence of LVH especially in resource limited settings where ECHO services are not readily available.

Hypertension doubles the risk for symptomatic CAD, including acute myocardial infarction and sudden death and more than triples the risk for CHF. Hypertension places increased tension on the left ventricular myocardium that is manifested as stiffness and hypertrophy, which accelerates

the development of atherosclerosis within coronary vessels [10].

The combination of increased demand and lessened supply increases the likelihood of myocardial ischemia and thereby leading to a higher incidence of myocardial infarction, sudden death, arrhythmias, and congestive failure in hypertensive patients. Endothelial dysfunction and chronic inflammation have been suggested as possible causes to explain the association between MA and cardiovascular disease. Microalbuminuria is an early manifestation of kidney damage and independently predicts cardiovascular disease (CVD). Left ventricular hypertrophy (LVH) is also an early marker of cardiac manifestation of target organ damage among hypertensive patients [12].

Conclusion

Authors found the presence of microalbuminuria in a significant number of newly detected and untreated patients of essential hypertension.

Treatment response in pulmonary tuberculosis patients: An observational study

Dr. Vipin Goyal

Associate professor, Department of Medicine, Ananta Institute of Medical Sciences and Research Center, Rajsamand, Rajasthan, India

ABSTRACT:

Background: Current drug regimens grew out of empiric observations and failure of early clinical strategies. Treating tuberculosis with streptomycin, isoniazid, or pyrazinamide monotherapy in the 1950s and 1960s led to an initial favorable response that was quickly abolished by the emergence of resistance. **Aim of the study:** To evaluate treatment response in pulmonary tuberculosis patients. **Materials and methods:** The study was conducted in the Department of General Medicine of the Medical Institute. A total of 100 patients were studied, information retrieved from the records includes socio-demographic profile of the patients; date of TB diagnosis and treatment outcome. All the patients underwent DOTS therapy for the treatment of pulmonary TB. **Results:** Mean age of the patients was 46.98 years. Number of male and female patients was 51 and 49 respectively. The number of PTB+ patients was 71 and the number of PTB- patients was 29. Successful treatment outcome was seen in 73% patients. Unsuccessful treatment outcome was seen in 27% patients. **Conclusion:** The treatment response is fairly successful. 29% patients had unsuccessful treatment response. Regular follow up of patients with unsuccessful treatment response and awareness creation through health education for rural patients in the course of treatment is vital.

Keywords: TB treatment, isoniazid, treatment outcome.

Introduction:

Current drug regimens grew out of empiric observations and failure of early clinical strategies. Treating tuberculosis with streptomycin, isoniazid, or pyrazinamide monotherapy in the 1950s and 1960s led to an initial favorable response that was quickly abolished by the emergence of resistance.[1-3] Use of combination therapy led to reduction in the emergence of drug resistance and became the standard for antituberculosis therapy.[4] A related rationale has been a belief that in cavitary tuberculosis, there are thought to be three populations of Mycobacterium tuberculosis: bacilli in log-phase growth, slowly replicating bacilli under acidic conditions, and nonreplicating bacilli under hypoxic conditions.[5] Drugs such as rifampin, isoniazid, and pyrazinamide are thought to have selective action on each of these populations, making it necessary to use multiple-drug therapy to eradicate all bacilli. Isoniazid is thought to kill bacilli in log-phase growth, whereas pyrazinamide is thought to kill slowly replicating bacilli during the first 2 months of the inital phase of therapy. Rifampin is thought to slowly kill nonreplicating persistent bacilli during the 6 months of therapy, with isoniazid added to prevent resistance during the continuation phase. These very popular concepts were developed to explain observed therapeutic actions of drugs, but have yet to be stated as falsifiable hypotheses and interrogated with use of modern experimental techniques.[6] Hence, the present

study was conducted to evaluate treatment response in pulmonary tuberculosis patients.

Materials and methods:

The study was conducted in the Department of General Medicine of the Medical Institute. The ethical clearance for the study was obtained from the ethical board of the institute prior to commencement of the study. For the study, we retrospectively viewed the medical records of the TB patients reporting at TB clinic of the medical hospital. A total of 100 patients were studied. Information retrieved from the records includes socio-demographic profile of the patients, date of TB diagnosis and treatment outcome. All the patients underwent DOTS therapy for the treatment of pulmonary TB. Data were collected in data collection format prepared for this purpose. In our study, smear-positive pulmonary TB (PTB+) was defined as patients with at least two positive sputum specimens for acid fast bacilli (AFB) by microscopy. Smear-negative pulmonary TB (PTB-) was defined as patients with symptoms suggestive of TB, with at least two sputum specimens which were negative for AFB by microscopy, and with chest radiographic abnormalities consistent with active PTB. The treatment outcome was categorized according to WHO as successful outcome and unsuccessful outcome. Success outcome was defined as cured TB patients (negative smear microscopy at the end of treatment and on at least one previous follow-up test) or completed treatment with resolution of symptoms. Unsuccessful outcome was defined as treatment failure (remaining smear-positive after 5 months of treatment), defaulted (patients who interrupted their treatment for two consecutive months or more after registration), or died.

The statistical analysis of the data was done using SPSS version 20.0 for windows. The Student's t-test and Chi-square test were used to check the significance of the data. The p-value less than 0.05 was predetermined as statistically significant.

Results:

A total of 100 TB patients were studied. Table 1 shows the demographic data of the patients. Mean age of the patients was 46.98 years. Number of male and female patients was 51 and 49 respectively. The number of PTB+ patients was 71 and the number of PTB- patients was 29. Table 2 shows the treatment outcome of TB patients. Successful treatment outcome was seen in 73% patients. Unsuccessful treatment outcome was seen in 27% patients. 7% patients were defaulted, 12 % died and 8% patients had treatment failure. On comparing the results were found to be statistically significant ($p<0.05$)[Fig 1 and 2].

Table 1: Demographic data of the patients

Parameters	Study group
Mean age (years)	46.98
Male/Female patients	51/49
No. of PTB+ patients	71
No. of PTB- patients	29

Fig 1: Demographics

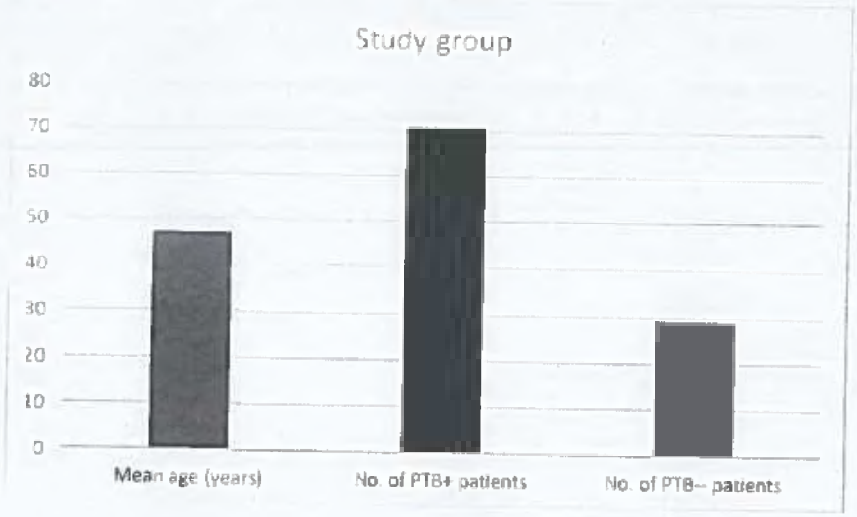

Table 2: Treatment outcome of TB patients

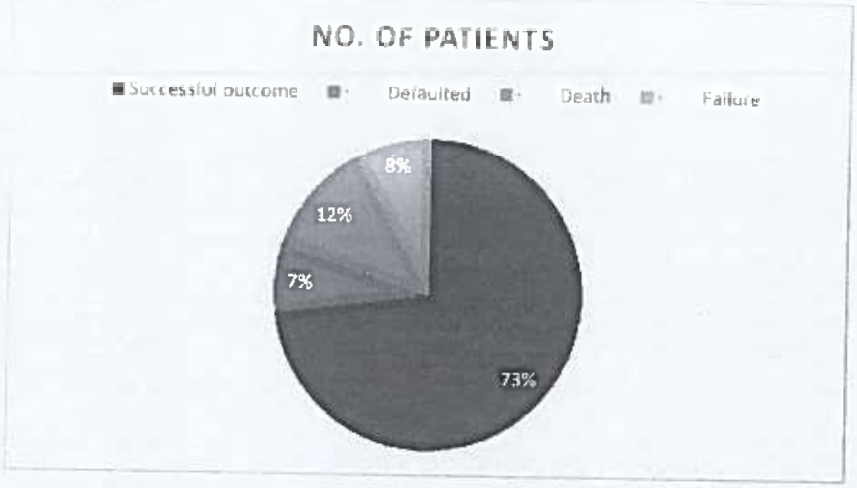
Treatment outcome	No. of patients	p-value
Successful outcome	73 (73%)	0.02
Unsuccessful outcome		
• Defaulted	7 (7%)	
• Death	12 (12%)	
• Failure	8 (8%)	

Fig 2: Treatment outcome



Discussion:

In the present study we evaluated treatment response in pulmonary tuberculosis patients. We observed that treatment response was successful in 71% of patients but unsuccessful in 29% patients. The results were statistically significant. The results were compared with previous studies and results were consistent with previous studies. Feleke BE et al assessed time to clinical response, the incidence density for clinical response and determinants of clinical response of tuberculosis (TB) patients in the intensive phases of TB treatment. Prospective cohort study design was implemented. The target population for this study was all patients following the directly observed therapy. Baseline data has been collected during the start of the directly observed TB treatment strategy. They have been collected updated data after the seven days of the baseline data collection, then after every seven days updated data has been collected from each pulmonary and extra pulmonary TB patients. Kaplan Meier curve was used to estimate time to clinical response. Incidence density using person days was used to estimate incidence of clinical response. Cox proportional hazard model was used to identify the predictors of clinical responses. A total of 1608 TB patients were included with a response rate at 99.5%. The mean age of the respondents was 24.5 years [standard deviation (SD) 14.34 years]. The incidence density for clinical response was 1429/38529 person days. One fourth of the TB patients showed clinical response at day 14, 25% of at day 21 and 75% a at day 31. Predictors of clinical response for TB patients includes: age), type of TB, Previous history of TB, Intestinal parasitic infection, hemoglobin, weight gain, Micronutrient supplementation, male sex. The clinical responses for extra-pulmonary TB patients were slower than pulmonary TB. Deworming and micronutrient supplementation should be considered as the additional TB treatment strategy for TB patients. Djoba Siawaya JF et al investigated the profiles of 30 proinflammatory, anti-inflammatory and angiogenic factors [epidermal growth factor, eotaxin, fractalkine, granulocyte colony-stimulating factor, granulocyte–macrophage colony-stimulating factor, interleukin (IL)-1α, IL-1β, IL-1ra, IL-2, IL-4, IL-5, IL-6, IL-7, IL-8, IL-10, IL-12p40, IL-12p70, IL-13, IL-15, IL-17, interferon-γ, interferon-inducible protein-10, Krebs von den Lungen-6, monocyte chemotactic protein-1, macrophage inflammatory protein (MIP)-1α, MIP-1β, sCD40L, transforming growth factor-α, tumour necrosis factor-α and vascular endothelial growth factor] in the plasma of 12 healthy tuberculin skin test-positive community controls and 20 human immunodeficiency virus-negative patients with active tuberculosis (TB) and

identified potential biomarkers for early treatment response. We showed differences in the level of circulating cytokines between healthy controls and TB patients, but also between fast responders and slow responders to anti-tuberculosis treatment. The general discriminant analysis based on pre-treatment and week 1 measurements identified 10 sets of three-variable models that could classify fast and slow responders with up to 83% accuracy. Overall, this study shows the potential of cytokines as indicators of anti-tuberculosis treatment response. [7, 8]

Abebe G et al investigated the treatment outcome and associated factors with an unsuccessful outcome at Jimma University Medical Center (JUMC), Southwest Ethiopia. A 5-year retrospective analytical study, including all types of TB cases who sought care at JUMC between September 1, 2012, and August 31, 2017, was conducted. Treatment outcomes and TB types were categorized according to the National TB Control guideline. Bivariate analysis was used to analyze the association between treatment outcome and potential variables. Overall data from 1249 patients' records were included in the study. The proportion of male patients was higher (815, 65.3%) than that of females. The mean age (± standard deviation, range) of the cases was 26 (±11. 6, 1-71) years. Of the total, 292 (23.3%) were smear-positive pulmonary TB (PTB), 489 (39.2%) smear-negative PTB, and 468 (37.5%) extra-PTB (EPTB) cases. Available treatment outcomes indicate that 253 (20.2%) were cured, 850 (68.0%) completed therapy, 58 (4.8%) died, 83 (6.6%) defaulted, and 5 (0.4%) failed the therapy. About 76 (5.6%) cases were transferred out and 44 (3.2%) cases were lost to follow-up. In total, 146 (11.7%) patients had an unsuccessful outcome. Unsuccessful treatment outcome was associated with smear-negative PTB, EPTB, and unknown human immunodeficiency virus (HIV) status. They concluded that the treatment success rate of overall TB patients is lower than end TB Strategy target of ≥90% success rate. Smear-negative PTB, EPTB cases, and those with unknown HIV status tend to have unsuccessful outcome. Gebrezgabiher G et al determined the treatment outcome of TB patients and investigate factors associated with unsuccessful outcome at Dilla University Referral Hospital, southern Ethiopia. Five years TB record of TB clinic of the hospital was reviewed. A total 1537 registered TB patients with complete information were included. Of these, 942 were male, 1015 were from rural areas, 544 were smear positive pulmonary TB (PTB+), 816 were smear negative pulmonary TB (PTB-) and 177 were extra pulmonary TB (EPTB) patients. Records of the 1537 TB patients showed that 181 (11.8%) were cured, 1129(73.5%) completed treatment, 171 (11.1%) defaulted, 52 (3.4%) died and 4 (0.3%) had treatment failure. The overall mean treatment success rate of the TB patients was 85.2%. The treatment success rate of the TB patients increased from 80.5% in September 2008-August 2009 to 84.8% in September 2012-May 2013. Tuberculosis type, age, residence and year of treatment were significantly associated with unsuccessful treatment outcome. The risk of unsuccessful outcome was significantly higher among TB patients from rural areas compared to their urban counterparts. Unsuccessful treatment outcome was also observed in PTB- patients and EPTB compared to the PTB+ patients. In conclusion, it appears that DOTS have improved treatment success in the hospital during five years. Regular follow-up of patients with poor treatment outcome and provision of health information on TB treatment to patients from rural area is recommended. [9, 10]

Conclusion:

Within the limitations of the present study, it can be concluded that the treatment response is fairly successful. 29% patients had unsuccessful treatment response. Regular follow up of patients with unsuccessful treatment response and awareness creation through health education for rural patients in the course of treatment is vital.

Assessment of Cases of Dengue Fever in Study Population- A Clinical Study

Vipin Goel[1], Virendra Kumar[2]

[1]Assistant Professor, Department of General Medicine, Saraswati Medical College Unnao, U.P., India,
[2]Associate Professor, Mayo Institute of Medical Sciences, Gadia, Barabanki, U.P., India

ABSTRACT:

Background: Dengue viruses are mosquito-borne flavi viruses that plagued people for centuries. Dengue fever (DF) and its more severe form i.e. dengue hemorrhagic fever (DHF), are caused by any one of the four serotypes of dengue virus belonging to the genus flavivirus transmitted by Aedes aegyptei. The present study was conducted to assess the cases of dengue in study population. **Materials & Methods:** This study was conducted in the department of general medicine in year 2015. It included 450 patients of both gender. After taking the history, clinical examination and laboratory investigation like complete hemogram, urea, creatinine, liver function test, chest, X-ray, ECG and ultra sound of abdomen was taken. Platelet counts were estimated. The diagnosis of pleural effusion was confirmed by X-chest. In ECG finding tachycardia was present in all the patients of shock and haemorrhage. All were subjected to serology NS1, IgM, IgG/IgM with rapid kit test. **Results:** Out of 450 patients, males were 220 and females were 230. The difference was non- significant (P-1). Age group 21-30 years consisted of 180 patients, age group 31-40 years had 135 patients, age group 41-50 years had 77 patients and >50 years had 58 patients. The difference was significant (P- 0.04). Common clinical manifestations in patients were fever (410), headache (250), myalgia (205), rash (157), bleeding (42), GIT manifestations (386) and shock (12). The difference was significant (P- 0.05). Platelets counts were <10000/cmm in 50 patients, <250000/cmm in 135 patients, <75000/cmm in 210 patients and 75000-150000/cmm in 55 patients. The difference was significant (P- 0.05). Serological test showed NS1 in 140 patients, IgM in 178 patients and IgG in 132 patients. Most of cases were seen in winters, September (125), October (210), November (70), December (35), January (5), February, may and july (1) each and September (2). The difference was significant (P- 0.05). **Conclusions:** Dengue is a viral fever caused by biting of mosquito. Proper care should be taken to avoid accumulation of water to prevent spread of mosquitoes. Bleeding, fever and decrease in platelets counts should be dealt seriously.

Key words: Aedes aegyptei, Dengue fever, flavi viruses

INTRODUCTION

Dengue viruses are mosquito-borne flavi viruses that plagued people for centuries. Dengue fever (DF) and its more severe form i.e. dengue hemorrhagic fever (DHF), are caused by any one of the four serotypes of dengue virus (DEN-1, DEN-2, DEN- 3, DEN-4) belonging to the genus flavivirus transmitted by Aedes aegyptei. Infection by one serotype generates life-long immunity against the same serotype, but gives transient/partial protection against the other serotypes.[1]

Sequential infection with another serotype can result in the more severe DHF. Immunology of Dengue Fever if characterized by an initial viremic phase which corresponds to the first 3 days of illness followed by a critical immune phase spanning from 3rd to 6th day of illness. The phase of dengue beyond 6th day of illness is called recovery phase. A sizable number of patients take longer to recover.[2]

During the febrile stage, people may also have: pain all over their bodies, headache a rash (this happens in 50% to 80% of people who get sick from dengue), petechiae (small red spots on the skin). These are caused by capillaries breaking. This makes the blood leak out and shows up under the skin. Small amounts of bleeding from the mucous membranes in the mouth and nose

The febrile stage usually lasts 2 to 7 days. This stage ends when a person's high fever is gone. It can cause altered mental status. This happens in 0.5% to 6% of people with very bad dengue fever. It can happen when the dengue virus causes an infection in the brain.[3] It can also happen when important organs, like the liver, are not working correctly

because of dengue. Neurological disorders involving brain and the nerves, like Guillain-Barré syndrome [5] and Post-dengue acute disseminated encephalomyelitis. Rarely, it can result into infection of the heart, or sudden liver failure.[6]
Dengue infection represents a considerable disease burden in many tropical and sub-tropical countries, particularly in children and young adults, living in urban and semi-urban areas. Globally about 50 million infections occur which is projected to increase. In endemic areas, dengue infection is a leading cause of hospitalisation and deaths among children.[5] The present study was conducted to assess the cases of dengue in study population.

MATERIALS & METHODS

This study was conducted in the department of general medicine in year 2015. It included 450 patients of both gender. All were informed regarding the study and written consent was taken. General information such as name, age, gender etc. was recorded in patients record file. After taking the history, clinical examination and laboratory investigation like complete hemogram, urea, creatinine, liver function test, chest, X-ray, ECG and ultra sound of abdomen was taken. Platelet counts were estimated. The diagnosis of pleural effusion was confirmed by X-chest. In ECG finding tachycardia was present in all the patients of shock and haemorrhage. All were subjected to serology NS1, IgM, IgG/IgM with rapid kit test. Results thus obtained were subjected to statistical analysis using chi-square test. P value ≤0.05 was considered significant.

RESULTS

Table I shows that out of 450 patients, males were 220 and females were 230. The diference was non- significant (P-1). Table II shows that age group 21-30 years consisted of 180 patients, age group 31-40 years had 135 patients, age group 41-50 years had 77 patients and >50 years had 58 patients. The difference was significant (P- 0.04). Graph I shows that common clinical manifestations in patients were fever (410), headache (250), myalgia (205), rash (157), bleeding (42), GIT manifestations (386) and shock (12). The difference was significant (P- 0.05). Graph II shows that platelets counts were <10000/cmm in 50 patients, <250000/cmm in 135 patients, <75000/cmm in 210 patients and 75000-150000/cmm in 55 patients. The difference was significant (P- 0.05). Graph III shows that serological test showed NS1 in 140 patients, IgM in 178 patients and IgG in 132 patients. Graph IV shows month wise distribution of patients. Most of cases were seen in winters, September (125), October (210), November (70), December (35), January (5), February, may and july (1) each and September (2). The difference was significant (P- 0.05).

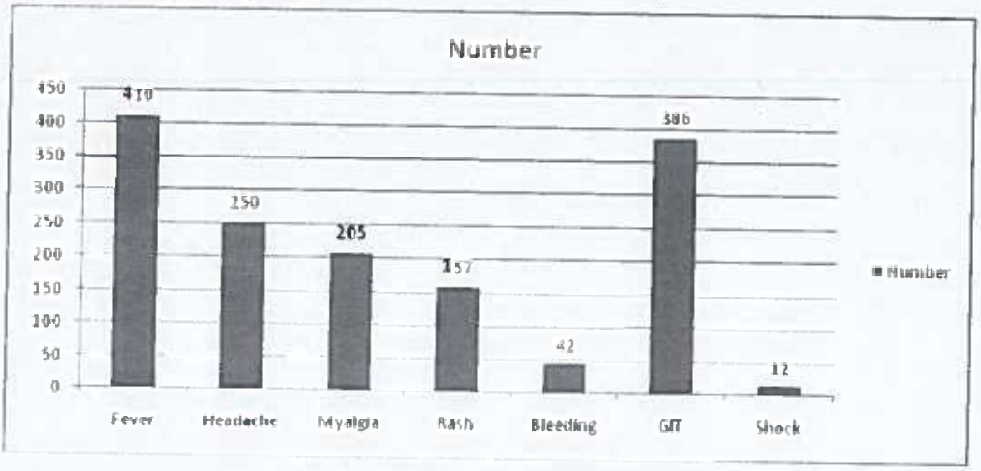
Table I Distribution of patients

Total - 450		
Males	**Females**	**P value**
220	230	1

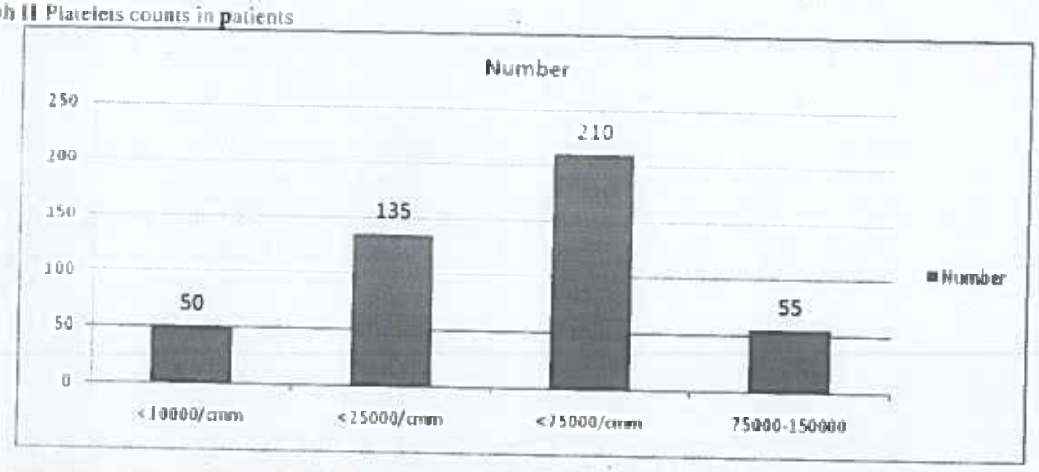
Table II Age wise distribution of patients

Age group	Number	P value
21-30	180 (40%)	0.04
31-40	135 (30%)	
41-50	77 (17%)	
>50	58 (12%)	

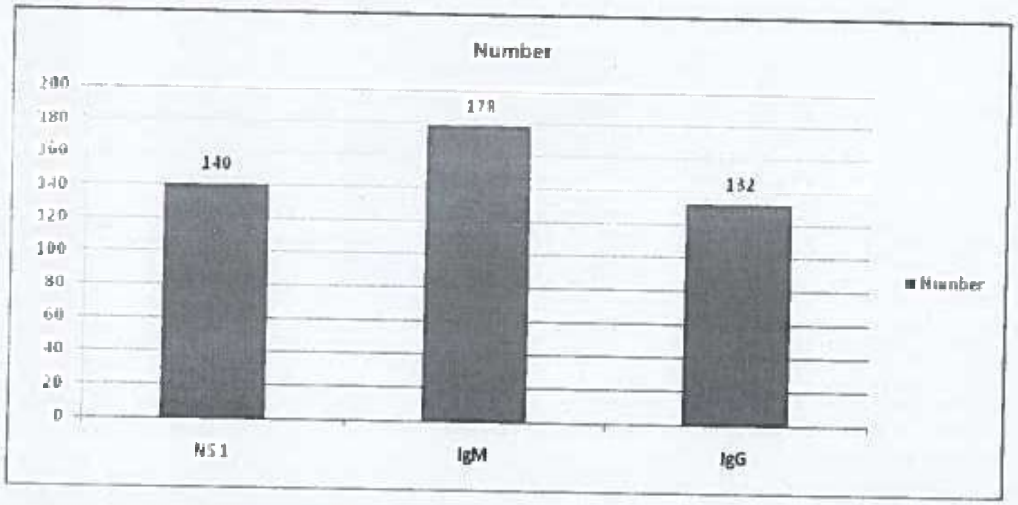
Graph I Clinical manifestations in patients



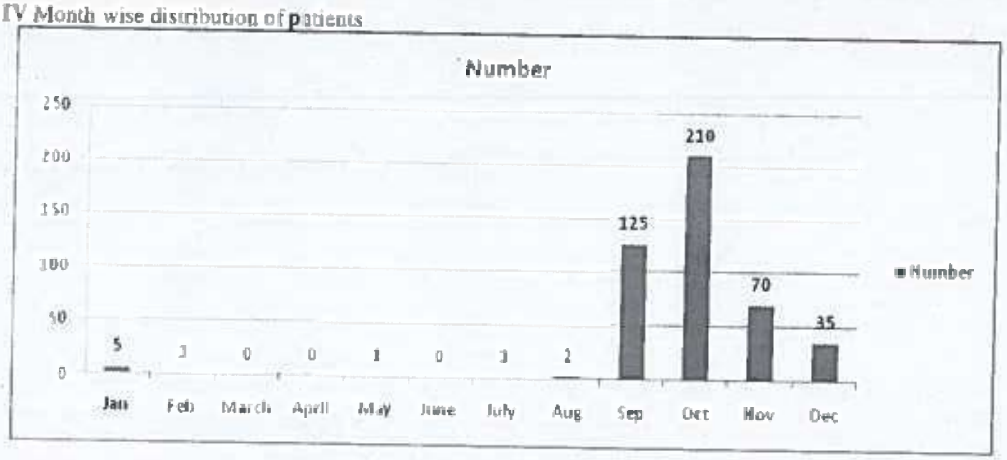
Graph II Platelets counts in patients



Graph III Serological distribution of Rapid test



Graph IV Month wise distribution of patients



DISCUSSION

In some people, the disease proceeds to a critical phase as fever resolves. During this period, there is leakage of plasma from the blood vessels, typically lasting one to two days. This may result in fluid accumulation in the chest and abdominal cavity as well as depletion of fluid from the circulation and decreased blood supply to vital organs.[5] This critical phase, while rare, occurs relatively more commonly in children and young adults. The present study was conducted to assess the cases of dengue in study population.

In our study, out of 450 patients, males were 220 and females were 230. Age group 21-30 years consisted of 180 patients, age group 31-40 years had 135 patients, age group 41-50 years had 77 patients and >50 years had 58 patients. This is in agreement with Scott.[7]

We found that common clinical manifestations in patients were fever, headache, myalgia, rash, bleeding, GIT manifestations and shock. There may also be organ dysfunction and severe bleeding, typically from the gastrointestinal tract. Shock (dengue shock syndrome) and hemorrhage (dengue hemorrhagic fever) occur in less than 5% of all cases of dengue, however those who have previously been infected with other serotypes of dengue virus ("secondary infection") are at an increased risk. This is in agreement with Sarkar JK.[8]

We observed that platelets counts were <10000/cmm in 50 patients, <250000/cmm in 135 patients, <75000/cmm in 210 patients and 75000-150000/cmm in 55 patients. Sharma S[9] in his study concluded that majority of patients shows low level of platelets and further decrease in its counts may be harmful. Serological test showed NS1 in 140 patients, IgM in 178 patients and IgG in 132 patients. Graph IV shows month wise distribution of patients. Most of cases were observed in october followed by september, november, December and january etc. DF is regulated by seasonal variations especially during monsoon period when there is abundant rainfall and high humidity, with daily temperature reaching 30°C.[10] These climatic conditions provide excellent ground for mosquito breeding.

CONCLUSION

Dengue is a viral fever caused by biting of mosquito. Proper care should be taken to avoid accumulation of water to prevent spread of mosquitoes. Bleeding, fever and decrease in platelets counts should be dealt seriously.

Epidemiological and Risk Factor Evaluation of Epileptic Patients: A Clinical Study

Vipin Goel[1], Virendra Kumar[2]

[1]Assistant Professor, Department of General Medicine, Saraswati Medical College Unnao, U.P., India,
[2]Associate Professor, Mayo Institute of Medical Sciences, Gadia, Barabanki, U.P., India

ABSTRACT:

Introduction: Epileptic seizures are one of the most emerging neurologic disorders worldwide. A number of etiologic factors are responsible for this. The major risk factors are cerebrovascular accidents and strokes followed by infections and tuberculosis. The goal of this study is to assess the prevalence of different etiologic agents in causation of epilepsy. **Material and methods:** The present prospective study was conducted with a sample size of 200 patients. A written consent was taken from all the patients and complete information was provided about the study. The data was collected from patients and analysis was done using SPSS software. **Results:** In the prospective study, the major cases of seizure patients were of cerebrovascular accident (45%), followed by Idiopathic (27%), Neuroinfection (15%), and alcohol withdrawal (4%). Whereas the stroke cases in elder age group was 62.5%. **Conclusion:** From the study we concluded that cerebrovascular accidents are the major etiologic factor responsible for seizure.

Keywords: Cerebrovascular, epilepsy, neuroinfection, seizure, stroke.

INTRODUCTION

A seizure is defined as a paroxysmal episode due to abnormal excessive and synchronous neuronal activity occurring in the brain. Epilepsy is emerging as one of the most serious neurological disorders worldwide. It is estimated that 5 to 10% of the overall world population will have atleast one seizure, predominantly occurring in infancy and late adulthood. The average range of epilepsy incidences is 0.3 – 0.5% in various populations throughout the world. These incidences are comparatively higher in developing countries like Africa and latin America than the developed countries like USA and Europe.[1] The all over prevalence of epilepsy incidences has been estimated as 5-10 individuals per 1000[2]. In the year 1997, WHO is association with International league against epilepsy and international bureau for epilepsy started a Global Campaign against epilepsy with noble approach. The chief etiology of epilepsy was cerebrovascular diseases, CNS infections and metabolic abnormalities. The tubercular meningitis; common type of chronic meningitis in India also presents with a manifestation of seizures.[3]The morality rate of the population is significantly associated with the comorbid conditions. The underlying etiology is signified with the very first attack of seizures.[4]. In southern part of India women usually presenting with headache and low grade fever have a cerebral venous thrombosis. Most commonly the focal seizure occur but they can eventually generalize to status epilepticus.[5] The aids for diagnosis plays a crucial role in the accuracy of made diagnosis. With advancement in technology, convenient and reliable diagnostic aids like magnetic resonance imaging (MRI) and video electroencephalogram (VEEG), are being used and even the smallest of structural abnormalities predisposing to epileptogenic foci are captured[6]. Thus a significant number of cases are found to be symptomatic. Through this hospital-based study we aim to assess the etiologic spectrum of symptomatic epilepsies, also as the hospital based studies are rare in the developing countries and this study will fill the voids in literature.

MATERIAL AND METHODS

This study selected 200 patients newly admitted to the hospital with complain of onset of seizures. Prior approval was obtained from the institutional ethical committee before the start of study. A written consent was also obtained from the subjects after giving them complete information about

the study.The clinical data of these patients were consecutively, systematically, and prospectively recorded in a database. Patients and eyewitness of the seizure episodes were questioned regarding the complete history and clinical examination was also done. Hb level, blood urea, serum creatinine, routine urine, TLC, DLC, ESR, RBS, Na/K/P/Ca were investigated in each patient. Also the MRI brain and CT scan was done in selective cases.

Inclusion Criterion

- Patients presenting with history of new onset seizures were included in the study
- Age of the patients must be above 3 years

Exclusion Criteria

Patients with associated problem of hyperventilation, psychogenic seizures, narcolepsy were excluded from the study

STATISTICAL ANALYSIS

After collecting all the data from patients, SPSS software was used to analyze the data arranged in tabulated form and the results were expressed as percentage of total.

RESULT

The study included of 200 subjects. In our study patient's average age ranged from18-90 years, with mean age of 45.78 years with SD 18.6. The general gender predilection of seizures was seen as male/female = 1.32/1.

The etiology of epileptic seizures is shown in TABLE 1. 45% of the total episodes of seizures were due to cerebrovascular accidents out of which 14 cases were due to haemorrhage and 8 cases were of infarcts. In 27% of the cases the etiology was unknown, therefore they were entitled as idiopathic. 4 cases were of subdural haemorrhage while 2 cases were of extradural haemorrhage. Neuroinfection was seen in 15% of cases. Out of which, 7% were of meningitis, 2% were of meningoencephalitis. 4 cases were of neurocysticercosis and 8 cases of tuberculosis of central nervous system. 4% seizures were seen in alcohol withdrawal cases. 5% cases were of metabolic causes for seizures. 1% cases of hypoglycemia were seen, 2 case each of uraemia and hyperglycemia were present. There were 4 cases of glioma and 2 cases each of secondaries and meningioma were seen. 4% of cases were of tumor induced seizures.

Fig. 1A shows the frequencies of different etiologies in seizure patients for the youngest age group (<18 years). In this age group CNS infection, MTS and CD were signified as most common causes of seizures. 55% of cases were of viral meningitis, whereas 12% cases were of tuberculosis and nuerocysticercosis. The cases of TBI were accounted for 10.4% cases and 8% cases were of encephalomalacia.

Fig. 1B depicts the frequencies of etiologies of seizures in the second age group of 18–50 years. TBI and infection were the primary causes in 40% of cases. While tuberculosis was seen in 32% of cases. Whereas 25% of cases were of neurocysticercosis.

Fig. 1C shows the frequency of different etiologies in the oldest age group (>50 years). In this age group ischemic stroke accounted as the predominant causes of seizure in whole of the population.

TABLE 1: Distribution of etiologies in patients with seizures (n=200)

Etiology	Number of cases	Percentage
1. Cerebrovascular accident	90	45
Infarcts	08	04
Haemorrhage	18	09
Old CVA with scar epilepsy	32	16
CVT	24	12
SDH	04	2
EDH	04	2
2. Idiopathic	54	27
3. Neuroinfection	30	15
Meningitis	14	7
Meningoencephalitis	04	2
CNS tuberculosis	8	4
Neurocisticercosis	4	2
4. Alcohol withdrawal seizure	8	4
5. Metabolic	10	5
Hypoglycemia	2	1
Hyperglycemia	4	2
Uraemia	4	2
6. Tumors	8	4
Glioma	4	2
Meningioma	2	1
Secondaries	2	1
7. Miscellaneous	2	1

Figure 1 A: Etiologic factor at < 18 years of age group

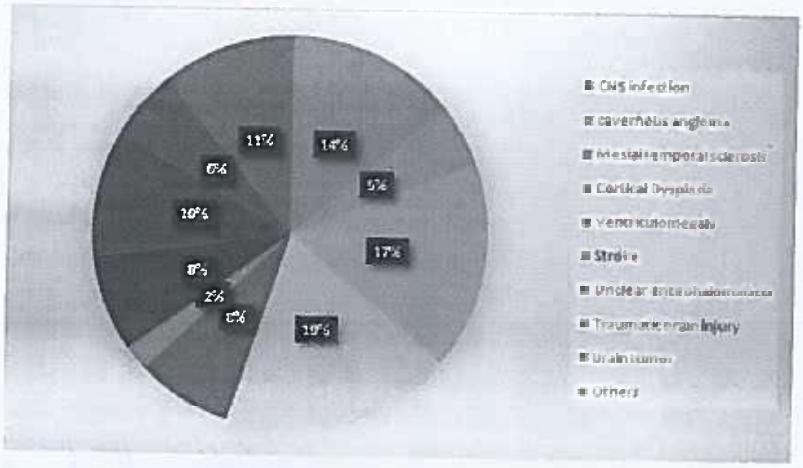

Figure 1 B: Etiologic factors in age group 18-50 years

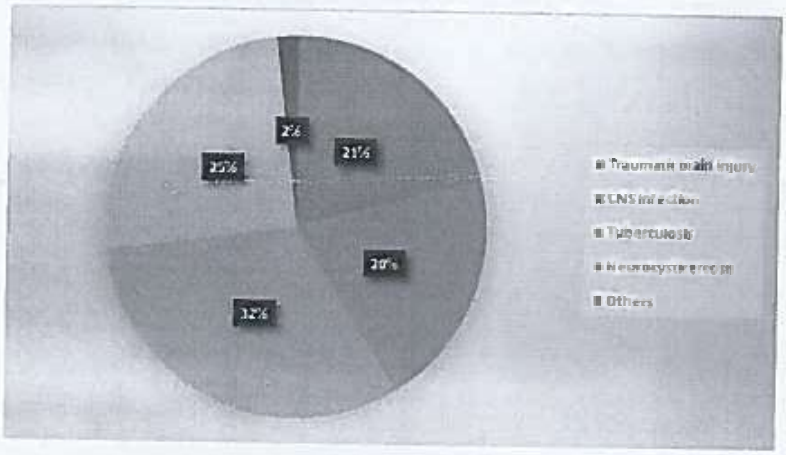

Figure 1C: Etiologic factors in age group of > 50 years

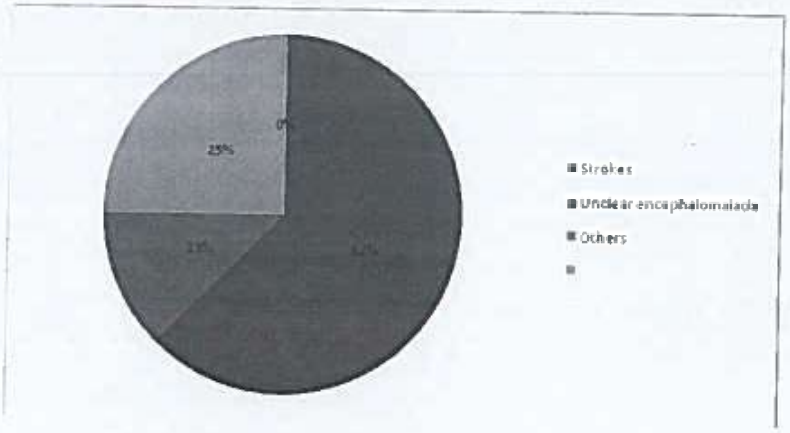

DISCUSSION

Seizures are common disorders found all over the world and are encountered frequently during medical practice in variety ofsettings. Patients from developing countries may represent the majority of all epilepsy cases worldwide because of the large gap in treatment availability and modernity.[2] The etiological spectrum of new onset symptomatic seizures and outcome may be different in developing countries when compared to developed countries. So this study on "seizures" was done to know the various etiologies of new onset seizures in adults in this region.

As compared to the outcomes of our study, in which 45% of seizure cases were due to cerebrovascular etiology, A study done by Sander[8] et al the vascular etiology was found only 15%, and in a study by Hauser[9] et al the figure was seen to be 18%. In our study only 4% of the cases were related to alcohol withdrawal which is less than that of Sander[8] et al study results of 9% and Chalasani S [9] et al results of 11%. According to a study by Shanker P saha[10] the CNS infection percentage was only 15.7% which is comparable to our results of 15%. There were 68.4% idiopathic cases which is more than our study results of 27% cases. Whereas in a study by Sinha S[11] et al the idiopathic cases were only 18.8%.

However it was seen that the most common etiology of seizure in elder age group remained to be stroke which is 62.5% in our study and 56.8% in a study done by Pandey[12] et al. In a study conducted by K. S. Amaravathi et al[13] and Sowntharyawt al[14] at a tertiary care hospital, the most common aetiology of seizures was Stroke, constituting to 38% of cases.

CONCLUSION

More than one third of newly diagnosed epilepsy cases were shown to be symptomatic via careful history-taking and laboratory examinations. Cerebrovascular accidents and strokes were the most common causes among symptomatic epilepsies in the study region. Given this etiological distribution, prevention strategies tailored to different age groups may be an efficient way for reducing the occurrence of seizures. The government should pay more attention to the social problems that contribute to provide the solutions.

ABSTRACT

Aims: To evaluate the correlation between serum bilirubin levels and coronary artery disease patients.

Material and methods: A cross-sectional study was conducted in the Department of medicine. Total of 100 subjects were included in the study with 50 cases and 50 controls. General and systemic examination was conducted on all study subjects including laboratory investigations like complete blood count, renal function test, lipid profile, viral markers such as HBsAG, HCVIgM and liver function test which includes total bilirubin, direct and indirect, liver enzymes, albumin and globulin levels.

Results: The entire study subjects were divided into two groups of 50 cases (with CVD) and 50 controls. The mean age among the cases male and female respectively was 62.6±5.8 and 63.2±7.9 and controls group were 61.9±9.6 and 62.9±7.7 years male and female respectively. 60% were male and 40% female in case group and 62% patients were male and 38% patients were female in control group. The most common risk factors for CVD like diabetes, hypertension, smoking, obesity and family history of CVD was found to be slightly higher among the cases than the control groups but it was not found to be statistically significant and it proves that the controls were matched for almost all the risk factors for CVD except for dyslipidemia which was found to be significantly higher among the CVD patients than the controls. The duration of CVD among the cases varied from 1 years to 10 years with majority of the subjects' duration was between 3 and 5 years and the mean duration was 4.7±2.7 years. For all the CVD patients an echocardiogram was performed and their ejection fraction was recorded and it was correlated with the serum bilirubin levels, authors found a perfect linear correlation between the ejection fraction and serum bilirubin levels, as the ejection fraction decreases the serum bilirubin levels was also decreasing and all the serum bilirubin parameters were found to be very low in patients with ejection fraction <50% when compared to patients with ejection fraction >60% and this association was found to be statistically significant ($p < 0.05$)

Conclusion: This study confirmed a significant inverse association between the reduced serum bilirubin levels and the occurrence of Coronary artery disease. Thus total bilirubin may serve as a protective biomarker of CAD.

Keywords: Coronary artery disease, Risk factor, Serum bilirubin

INTRODUCTION

In recent years, the incidence of cardiovascular disease has increased gradually in developing nations.[1] Coronary artery disease has received most attention from medical workers because of its high fatality rate, especially the acute onset of coronary artery disease. The current scenario necessitates the recognition of novel risk factors and screening of individuals who are at risk of developing CAD.[2] In spite of detailed studies on many established risk factors

ISSN: 0975-3583,0976-2833 VOL12, ISSUE 06, 2021

like diabetes mellitus, hypertension, smoking, dyslipidemiaetc, the studies on serum bilirubin and its pre disposition to CAD are worth a consideration. Postulated cardio protective effects of bilirubin are Has antioxidant properties that inhibit oxidation of LDL and lower LDL levels[3] Preserves vascular nitric oxide that maintains vessel wall elasticity Has anti-inflammatory benefits and inhibits platelet activation and aggregation properties that prevent thrombus formation suppresses matrix metalloproteinases and maintains vascular integrity Several studies have concluded inverse correlations between CAD and total serum bilirubin levels.[4] Also inverse correlation between serum bilirubin and smoking, increased LDL cholesterol, diabetes and increased BMI have been documented. Lesser serum bilirubin levels are associated with Protein Kinase C activation, inflammation, and oxidative stress, which are known mediators of endothelial and micro vascular dysfunction. [5] Very few studies in India had been conducted to prove the association between serum bilirubin levels and coronary artery disease and so the present study was undertaken to assess the association between these two variables by comparing it with a control group.

Many factors increase the risk of CAD, including low serum bilirubin level, which is associated with increased risk of CAD.[6]Several studies have shown that bilirubin, the final product of hem metabolismhas potent antioxidant capacity.[7] A study performed on healthy individuals. Dividing them according to serum bilirubin levels into 3 groups of low, intermediate and high, has shown that high bilirubin level prevents coronary flow reserve impairment, microvascular dysfunction and probably coronary atherosclerosis.[8] Epidemiologic studies have indicated that the total bilirubin level is inversely related to diabetes mellitus, hypotension, CAD and metabolic syndrome.[9,10] Atherosclerosis and inflammation are associated with free oxygen and peroxyl radicals' formation.[11,12] Arterial protective responses and adjustment against oxidative stress have important roles in atherosclerosis prevention.[13] Studies have shown that different forms of circulating bilirubin and its precursor, biliverdin, have the ability to remove the reactive forms of oxygen. They also prevent the oxidation of low-density-lipoprotein particles and monocyte chemotaxis all which are considered as stages of atherosclerosis.[14,15] Very few studies in India had been conducted to prove the association between serum bilirubin levels and coronary artery disease and so the present study was undertaken to assess the association between these two variables by comparing it with a control group.

MATERIAL AND METHODS

A cross-sectional study was conducted in the Department of medicine, after taking the approval of the protocol review committee and institutional ethics committee. After taking informed consent detailed history was taken from the patient or the relatives. The technique, risks, benefits, results and associated complications of the procedure were discussed with all patients. Patients with evidence of coronary artery disease by ECG, ECHO were included in this study. Patients with symptoms of congestive cardiac failure, Chronic kidney disease, Chronic liver disease, autoimmune diseases and COPD and malignancy were excluded from the study.

Total of 100 subjects were included in the study with 50 cases and 50 controls. General and systemic examination was conducted on all study subjects including laboratory investigations like complete blood count, renal function test, lipid profile, viral markers such as HBsAG, HCVIgM and liver function test which includes total bilirubin, direct and indirect, liver enzymes, albumin and globulin levels. A 12 lead ECG and a transthoracic echocardiogram was performed for all patients. Total serum bilirubin was measured in the laboratory by spectrophotometry method. In the Jendrassik-Grof allied methods, total bilirubin is reacted with diazotized sulfanilic acid in an acidic medium to form azobilirubin. The absorbance of the azo pigment is then measured as direct bilirubin and the total bilirubin is measured after

ISSN:0975-3583.0976-2833 VOL12, ISSUE 06, 2021

treatment with alkaline tartrated solution, which shifts the maximum absorption of the azo pigment towards longer wavelength.

STATISTICAL ANALYSIS

All the data were entered and analysed using SPSS version 25.0. Mean and standard deviation was derived for all the parametric variables and the parametric variables between the two groups (cases and controls) were compared using unpaired student T test and comparison between the frequencies was done by using chi-square test considering $p \leq 0.05$ as statistically significant

RESULTS

The entire study subjects were divided into two groups of 50 cases (with CVD) and 50 controls. Table 1 shows the mean age and sex distribution of the study subjects. Majority of the patients were in the age group between 50-60 years. The minimum age was 41 and the maximum age was 72 years. The mean age among the cases male and female respectively was 62.6±5.8 and 63.2±7.9 and controls group were 61.9±9.6 and 62.9±7.7 years male and female respectively. 60% were male and 40% female in case group and 62% patients were male and 38% patients were female in control group and So, it shows that the cases and controls did not show any significant difference with respect to age and gender which implies that the controls were age and sex matched.

Table 1: Demographic profile of the patients

Age group	Cases=50		Controls=50	
	Males=30	Females=20	Males=31	Females=19
Mean±SD	62.6±5.8	63.2±7.9	61.9±9.6	62.9±7.7

The most common risk factors for CVD like diabetes, hypertension, smoking, obesity and family history of CVD was found to be slightly higher among the cases than the control groups but it was not found to be statistically significant and it proves that the controls were matched for almost all the risk factors for CVD except for dyslipidemia which was found to be significantly higher among the CVD patients than the controls (Table 2).

Table 2: risk factors for CVD Patients

Risk factors	Cases (n=50)	Controls (n=50)	P value
Diabetes	16 (32%)	14 (28%)	0.33
Hypertension	27 (54%)	21 (42%)	0.15
Smoking	18 (36%)	17 (34%)	0.86
Family history of CVD	21 (42%)	32 (32%)	0.27
Obesity	13 (26%)	10 (20%)	0.18
Dyslipidemia	31 (62%)	21 (42%)	0.003

Table 3: Distribution of the patients based on their duration of CVD.

Duration of CVD	Number of patients =50	%	Mean±SD
Below 3 years	10	20%	
3 - 5 years	25	50%	
5 - 7 years	11	22%	4.7±2.7
Above 7 years	4	8%	

ISSN: 0975-3583,0976-2833 VOL12, ISSUE 06, 2021

The duration of CVD among the cases varied from 1 years to 10 years with majority of the subjects' duration was between 3 and 5 years and the mean duration was 4.7±2.7 years. The patients' CVD status was confirmed by history, ECG findings and ECHO reports (Table 3).
The various liver function test parameters were compared between the cases and controls it was found that the serum bilirubin levels which includes total bilirubin, direct bilirubin and indirect bilirubin was found to be lower among the case group compared to the control group and this difference was found to be statistically significant, whereas the other parameters like SGOT, SGPT and GGT levels did not show much difference between the case and control groups and the difference in values were not statistically significant (Table 4).

Table 4: Comparison of the liver function test parameters between the CVD patients and the controls.

LFT	Cases (mean±SD)	Controls (mean±SD)	P value
Total bilirubin	0.89±0.03	1.21±0.22	<0.001
Direct bilirubin	0.23±0.05	0.49±0.15	<0.001
Indirect bilirubin	0.71±0.14	0.88±0.18	<0.001
SGOT (IU/L)	10	17	0.59
SGPT (IU/L)	17	15	0.21
GGT (IU/L)	23	18	0.31

For all the CVD patients an echocardiogram was performed and their ejection fraction was recorded and it was correlated with the serum bilirubin levels, authors found a perfect linear correlation between the ejection fraction and serum bilirubin levels, as the ejection fraction decreases the serum bilirubin levels was also decreasing and all the serum bilirubin parameters were found to be very low in patients with ejection fraction <50% when compared to patients with ejection fraction >60% and this association was found to be statistically significant ($p < 0.05$) (Table 5).

Table 5: Correlation between serum bilirubin levels and the ejection fraction among the CVD patients.

Serum bilirubin	>60 % (n= 12)	50-60 % (n=28)	<50 % (n=10)	P value	r value
Total bilirubin (mean±SD)	1.5±0.25	0.85±0.19	0.73±0.19	<0.001	0.91
Direct bilirubin (mean±SD)	0.41±0.14	0.33±0.16	0.21±0.06	<0.001	0.88
Indirect bilirubin (mean±SD)	0.72±0.23	0.65±0.17	0.59±0.07	<0.001	0.93

DISCUSSION

Atherosclerosis is considered to be the most common underlying cause for the coronary artery disease (CAD), which is the major cause of mortality worldwide both in developed and developing countries. Whereas on the other hand antioxidants are the predominant adaptive responses by the arterial vasculature in response to the oxidative stress thereby preventing the atherosclerosis.[16] Bilirubin, being a toxic waste product formed during heme catabolism is in fact a potent physiological antioxidant that provides important protection against atherosclerosis and inflammation.[17] A particular enzyme namely the hemeoxygenase (HO) is a stress inducible enzyme in the heme catabolism which plays an important role in cell defense mechanism against oxidative injury.

ISSN: 0975-3583,0976-2833 VOL12, ISSUE 06, 2021

The products of the catabolic reaction, i.e. bilirubin, carbon monoxide and iron have a protective role. The other important role of bilirubin, the natural antioxidants are the inhibition of vascular cell adhesion molecule VCAM-1 preventing the proliferation of the smooth muscle cells and the transendothelial migration of the leucocytes.[18]

Plasma bilirubin inversely correlated with risk factors of CAD- smoking, diabetes and obesity, thus emphasizing the oxidative stress underlying in them, but in present study authors did not observed such correlation as authors matched most of the risk factors between the cases and controls. Inverse relationship between the presence of CAD and circulatory total bilirubin was first observed by Schwertneret al.[19]

Male gender is one of the most important risk factors for CAD. In this study The mean age among the cases male and female respectively was 62.6±5.8 and 63.2±7.9 and controls group were 61.9±9.6 and 62.9±7.7 years male and female respectively. 60% were male and 40% female in case group and 62% patients were male and 38% patients were female in control group and So, it shows that the cases and controls did not show any significant difference with respect to age and gender which implies that the controls were age and sex matched. We also matched other comorbidities thereby removing the confounding factors responsible for the lowering of bilirubin as a result of the oxidative stress and other mechanisms.[20]

Present study found a significant inverse association between serum bilirubin and CAD in comparison with control, bilirubin levels found to be significantly lower in CAD patients in comparison with the controls ($p < 0.001$) and a similar type of results was also quoted by Taban SM et al. and in their study they had also found a significant association between the bilirubin levels and the severity of CAD by doing an angiogram.[21] So it seems that higher bilirubin level has a protective effect against coronary artery stenosis (CAS).

The present study among 50 CAD patients and 50 healthy controls confirmed the results of several previous epidemiological studies that low serum bilirubin levels were associated with increased risk for coronary events.[22,23,24] A recent study in patients with peripheral arterial disease (PAD) revealed similar results showing a clear association between low bilirubin concentrations and PAD.[25] Present study showed a higher level of mean total bilirubin in males in comparison to females, but the difference was not statistically significant, however lower levels of bilirubin in females may be attributed to the influence of estrogens. This may relate to the increased secretion of bilirubin through the induction of UDP-glucuroniltransferasa enzyme in liver. Estrogens also decrease LDL level, increase HDL level and reduce LDL oxidation.[26]Recently, low serum bilirubin levels have been proposed as a useful biomarker to predict cardiovascular risk and suggests that bilirubin acts as a potent physiologic antioxidant and anti-inflammatory agent. Studies have shown that elevated serum bilirubin concentrations provide important protection against atherosclerotic diseases.[16]Several authors have suggested that bilirubin plays a potential role in inhibition of lipid oxidation.[27] An inverse correlation between the presence of coronary artery disease, peripheral arterial disease, carotid intima-media thickness and bilirubin has been reported in several studies. Subnormal levels of plasma bilirubin are associated with premature coronary artery disease and cardiovascular morbidity.[28] In a previous study, the 3-year incidence of coronary artery disease was significantly lower in patients with Gilbert syndrome.[29] This study showed a significant relation between ejection fraction with total serum bilirubin the ejection fraction showed a descending trend as serum bilirubin level decreased and a similar type of results was also quoted by Taban SM et al.[21]

CONCLUSION

This study confirmed a significant inverse association between the reduced serum bilirubin levels and the occurrence of Coronary artery disease. Thus total bilirubin may serve as a protective biomarker of CAD.

Abstract

Background: Thyroid disorders are reported in higher magnitude among women than men. Various reports have shown an increasing trend of thyroid disorders with an increase in age. Occurrence of thyroid disorders such as hypothyroidism, autoimmunity, nodular goiter, and cancer was the most often reported in post-menopausal and elderly women than younger women. **Material & Methods:** 100 post-menopausal women of age group 50-55 years according to inclusion and exclusion criteria and 100 pre-menopausal women of age group 34-49 years according to inclusion and exclusion criteria were enrolled in the present study. Study participants were enrolled by simple random sampling. Clearance from the hospital ethics committee was taken before the start of the study. Written informed consent was taken from each study participant. **Results:** In the present study, out of total study participants, based on the thyroid function test status, the mean value of total T3 among pre-menopausal group was 142.4±10.9 and the mean value of total T3 among post-menopausal group was 169.4±11.8, the mean value of total T4 among pre-menopausal group was 8.1±1.3 and the mean value of total T4 among post-menopausal group was 9.3±1.2, the mean value of TSH among pre-menopausal group was 12.4±4.8 and the mean value of TSH among post-menopausal group was 20.4±5.1, the mean value of free T3 among pre-menopausal group was 286±13.4 and the mean value of free T3 among post-menopausal group was 312±15.6 the mean value of free T4 among pre-menopausal group was 1.23±1.1 and the mean value of free T4 among post-menopausal group was 1.38±1.2. **Conclusion:** We concluded from the present study that thyroid dysfunction suggesting from the thyroid profile in post-menopausal women. We recommend the thyroid profile of all post-menopausal women to diagnose and treat the thyroid dysfunction early.

Keywords: Thyroid dysfunction, post-menopausal women, pre-menopausal women.

Introduction

It is well established in various researches that thyroid hormones function a very important role in the development, regulation of metabolism, protein synthesis, and functioning of other hormones[1]. The thyroid gland is a butterfly-shaped endocrine gland that is situated anatomically in the anterior aspect of the root of the neck and comprises two bulky lateral lobes which are connected by a thin isthmus[2]. The thyroid gland secretes several hormones such as triiodothyronine

(T3), thyroxine (T4), and calcitonin. The prevalence and magnitude of all thyroid disorders are associated and dependent on numerous risk factors and confounding factors[3].

The thyroid hormones control the metabolism of macromolecules, oxygen consumption, and the basal metabolic rate (BMR) of body cells and are essential for normal growth and maturation of the body as well as they are essential for proper development of the peripheral and central nervous system[4]. Peripheral metabolism of thyroid hormones and pituitary-thyroid axis reported to be affected in various diseases and characterized by the Low T3 levels which are followed by subclinical hypothyroidism findings[5].

Thyroid disorders are reported in higher magnitude among the general population, although their prevalence is also high reported among women than men. Various reports have shown an increasing trend of thyroid disorders with the increase in age[6]. Occurrence of thyroid disorders such as hypothyroidism, autoimmunity, nodular goiter, and cancer was the most often reported in post-menopausal and elderly women than younger women[7]. We conduct the present study to assess the thyroid dysfunction among pre-and post-menopausal women at our tertiary care hospital.

Materials and methods

The present cross-sectional, observational study was conducted at the department of general medicine of our tertiary care hospital. The study was an observational study conducted during a period of six months. The study was done at a 90% confidence interval at 10% of maximum allowable error. The sample size of 200 patients was calculated by epi info software. 100 post-menopausal women of age group 50-55 years according to inclusion and exclusion criteria and 100 pre-menopausal women of age group 34-49 years according to inclusion and exclusion criteria were enrolled in the present study. Study participants were enrolled by simple random sampling. Clearance from the hospital ethics committee was taken before the start of the study. Written informed consent was taken from each study participant.

For the study purpose, any woman who had no menstruation for a minimum period of 1-year duration was considered a post-menopausal woman. Previously diagnosed cases of thyroid disorders, diabetes mellitus, hypertension, obesity, and systemic diseases were excluded from the present study. All the study participants were subjected to general physical and clinical examination and detailed history was recorded from all of them. All the study participants were subjected to routine blood investigation for complete blood count and thyroid function tests. All the recorded data was entered in an Excel spreadsheet on Microsoft Excel 2016. The statistical analysis was done using the Statistical software package SPSS v22 and Epi Info v7.2. A p-value <0.05 with 95% confidence intervals was considered statistically significant.

Results

In the present study we enrolled a total of 100 post-menopausal women of age group 50-55 years according to inclusion and exclusion criteria and 100 pre-menopausal women of age group 34-49 years according to inclusion and exclusion criteria were enrolled in the present study. Among the study participants, all the women in the pre-menopausal group were ranged from age 34 to 49 years with a mean age of 42.4 ± 5.6 years. All the women in the post-menopausal group were ranged from age 51 to 55 years with the mean age of 52.9 ± 1.8 years. Out of the total study participants, among all the women in the pre-menopausal group, 8% had hyperthyroidism, 34% had hypothyroidism and 58% had normal thyroid functions. Among all the women in the post-menopausal group, 11% had hyperthyroidism, 39% had hypothyroidism

and 50% had normal thyroid functions. (Table 1)

Table 1: Distribution of study subjects according to the thyroid profile.

Thyroid disorders	post-menopausal group	pre-menopausal group	P value
Hyperthyroid	11%	8%	>0.05
Hypothyroid	39%	34%	
Normal	50%	58%	

In the present study, out of total study participants, based on the thyroid function test status, the mean value of total T3 among the pre-menopausal group was 142.4 ± 10.9 and the mean value of total T3 among the post-menopausal group was 169.4 ± 11.8. the mean value of total T4 among the pre-menopausal group was 8.1 ± 1.3 and the mean value of total T4 among the post-menopausal group was 9.3 ± 1.2. the mean value of TSH among the pre-menopausal group was 12.4 ± 4.8 and the mean value of TSH among the post-menopausal group was 20.4 ± 5.1. the mean value of free T3 among the pre-menopausal group was 286 ± 13.4 and the mean value of free T3 among post-menopausal group was 312 ± 15.6. the mean value of free T4 among pre-menopausal group was 1.23 ± 1.1 and the mean value of free T4 among post-menopausal group was 1.38 ± 1.2. All these differences between both groups were statistically non-significant.(Table 2)

Table 2: Thyroid dysfunction among study participants.

Thyroid function test	post-menopausal group	pre-menopausal group	P value
Total T3	169.4 ± 11.8	142.4 ± 10.9	>0.05
Total T4	09.3 ± 1.2	08.1 ± 1.3	>0.05
TSH	20.4 ± 5.1	12.4 ± 4.8	>0.05
Free T3	312 ± 15.6	286 ± 13.4	>0.05
Free T4	01.38 ± 1.2	01.23 ± 1.1	>0.05

Discussion

In the present study we enrolled a total of 100 post-menopausal women of age group 50-55 years according to inclusion and exclusion criteria and 100 pre-menopausal women of age group 34-49 years according to inclusion and exclusion criteria were enrolled in the present study. Among the study participants, all the women in pre-menopausal group were ranged from age 34 to 49 years with a mean age of 42.4±5.6 years. All the women in post-menopausal group were ranged from age 51 to 55 years with the mean age of 52.9±1.8 years. Similar results were obtained in a study conducted by Shetty AGN et al among 50 post-menopausal women of age group 50-55 years according to inclusion and exclusion criteria and 50 pre-menopausal women of age group 34-49 years. They reported similar findings as to the present study[8]. Similar results were obtained in a study conducted by Kapadia N et al among 50 post-menopausal women of age group 50-55 years according to inclusion and exclusion criteria and 50 pre-menopausal women of age group 34-49 years. They reported similar findings as to the present study[9].

In the present study, based on the thyroid function test status, out of the total study participants, among all the women in pre-menopausal group, 8% had hyperthyroidism, 34% had hypothyroidism and 58% had normal thyroid functions. Among all the women in post-menopausal group, 11% had hyperthyroidism, 39% had hypothyroidism and 50% had normal thyroid functions. Similar results were obtained in a study conducted by G.

Bordoloi et al among 304 post-menopausal women of age group 50-55 years according to inclusion and exclusion criteria and pre-menopausal women of age group 34-49 years. They reported similar findings as the present study[10]. Similar results were obtained in a study conducted by Garg N et al among 100 post-menopausal women of age group 50-55 years according to inclusion and exclusion criteria. They reported similar findings as the present study[11].

In the present study, out of total study participants, based on the thyroid function test status, the mean value of total T3 among pre-menopausal group was 142.4±10.9 and the mean value of total T3 among post-menopausal group was 169.4±11.8, the mean value of total T4 among pre-menopausal group was 8.1±1.3 and the mean value of total T4 among post-menopausal group was 9.3±1.2, the mean value of TSH among the pre-menopausal group was 12.4±4.8 and the mean value of TSH among the post-menopausal group was 20.4±5.1, the mean value of free T3 among the pre-menopausal group was 286±13.4 and the mean value of free T3 among the post-menopausal group was 312±15.6, the mean value of free T4 among the pre-menopausal group was 1.23±1.1 and the mean value of free T4 among the post-menopausal group was 1.38±1.2. All these differences between both groups were statistically non-significant. Similar results were obtained in a study conducted by Chetna P et al among post-menopausal women of age group 50-55 years according to inclusion and exclusion criteria and pre-menopausal women of age group 34-49 years. They reported similar findings as to the present study[12].

Conclusion

We concluded from the present study that thyroid dysfunction suggesting from the thyroid profile in post-menopausal women. We recommend the thyroid profile of all post-menopausal women to diagnose and treat thyroid dysfunction early.

Abstract

Background: Tuberculosis (TB) is one of the major infectious disease and health concern in the world. The present study was conducted to assess cases of pulmonary tuberculosis **Materials & Methods:** 238 diagnosed cases of active TB of both genders were included. Contact history, primary disease or recurrence, complaints at admission, Bacillus Calmette-Guerin (BCG) vaccination, clinical findings and involvement sites were recorded. **Results:** Out of 238 patients, males were 138 and females were 100. <25 years had 110 and 25-40 years had 128 patients. Fever was present in 203, fatigue in 156, weight loss in 82, cough in 118 and hemoptysis in 73 patients. Involved area was lymph nodes such as cervical in 30, inguinal in 54, mediastinum in 28, axillary in 52, paratracheal in 22, omentum in 18, peritoneum in 10, vertebra in 6, wrist in 8, skin in 5 and CNS in 5 cases. The difference was significant ($P < 0.05$). **Conclusion:** Maximum cases were seen in males and common site was inguinal lymph node.

Key words: Tuberculosis, inguinal lymph node, hemoptysis

Introduction

Tuberculosis (TB) is one of the major infectious disease and health concern in the world. TB is a bacterial disease caused by Mycobacterium tuberculosis and infrequently by Mycobacterium africanum and Mycobacterium bovis[1]. TB pathogens are slow growing, fastidious, hydrophobic and lipid-rich bacteria that have acid fast rod shape which prevent decolorization with acid alcohol[2]. It is a chronic contagious infection that not only affects humans but a wide range of mammals. The main way of spread occurs by airborne transmission and infectious droplets[3]. A person with TB who is coughing is the key source of infection. The infectiousness of a person with TB disease is directly related to the number of tubercle bacilli that he or she expels into the air. Persons who expel many tubercle bacilli are more infectious than patients who expel few or no bacilli[4].

Mycobacteria invade many organs during primary infection, but these foci remain dormant (without disease development) if the host has an effective immune system. Reactivation is accelerated in patients with latent diseases, under conditions where the immune system is suppressed[5]. The risk of EPTB and mycobacteremia increases with advancing immunosuppression. Extrapulmonary involvement can be seen in >50% of patients with concurrent AIDS and TB. EPTB includes TB of organs other than the lung parenchyma, such as the lymph nodes, pleura, abdomen, genitourinary tract, gastrointestinal tract, skin, joints and bones, or meninges.

The diagnosis of EPTB is more difficult than that of PTB. Its increasing incidence and severe sequelae due to the delay in diagnosis lead to a significant decrease in labor force[6]. The present study was conducted to assess cases of pulmonary tuberculosis.

Materials & Methods

The present study was conducted among 238 diagnosed cases of active TB of both genders. All patients were enrolled with their written consent. Ethical committee approval was obtained from institutional review committee.

Patient data such as name, gender, age, contact history, primary disease or recurrence, complaints at admission, Bacillus Calmette-Guerin (BCG) vaccination, clinical findings and involvement sites were recorded. Active TB was defined as an identification of M. tuberculosis through Ziehl-Neelsen acid-fast stain and culture in Lowenstein Jensen or BACTEC media in a tissue or infected specimen in culture-positive patients. Results of the study was subjected to statistical analysis. P value less than 0.05 was considered significant.

Results

Table 1 Distribution of patients

Total- 238		
Gender	Male	Female
Number	138	100

Table 1 shows that out of 238 patients, males were 138 and females were 100.

Table II Assessment of parameters

Parameters	Variables	Number	P value
Age group (Years)	<25	110	0.12
	25-40	128	
Clinical features	Fever	203	0.01
	Fatigue	156	
	Weight loss	82	
	Cough	118	
	Hemoptysis	73	
Involved area	Cervical	30	0.04
	Inguinal	54	
	Mediastinum	28	
	Axillary	52	
	Paratracheal	22	
	Omentum	18	
	Peritoneum	10	
	Vertebra	6	
	Wrist	8	
	Skin	5	
	CNS	5	

Table II, graph I shows that <25 years had 110 and 25-40 years had 128 patients. Fever was present in 203, fatigue in 156, weight loss in 82, cough in 118 and hemoptysis in 73 patients. Involved area was lymph nodes such as cervical in 30, inguinal in 54, mediastinum in 28, axillary in 52, paratracheal in 22, omentum in 18, peritoneum in 10, vertebra in 6, wrist in 8, skin in 5 and CNS in 5 cases. The difference was significant (P< 0.05).

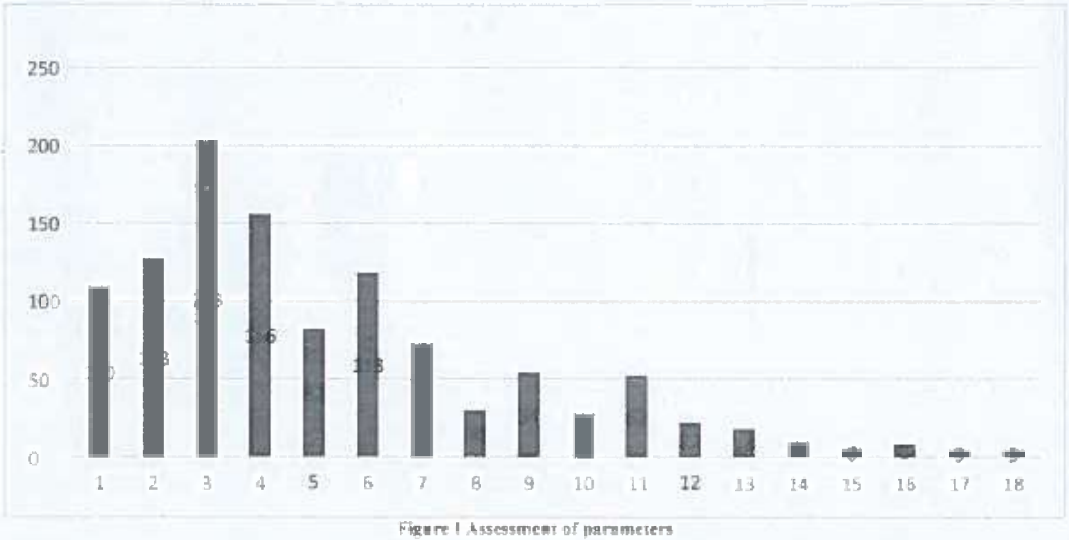

Figure I Assessment of parameters

Discussion

Tuberculosis (TB) is a major global health problem and may appear as a multisystem disease. It is a chronic necrotizing bacterial infection characterized by the presence of granulomatous lesions, caused by the Mycobacterium tuberculosis complex[7]. This includes M. africanum, M. microti, M. tuberculosis, and M. bovis. M. tuberculosis is responsible for 97-99% of disease development. TB has two sequential processes: infection and active disease. Active disease can develop during any period of life in approximately 10% of the subjects who have been infected with the TB bacillus[8]. The disease may involve any or all organs, but the lungs are the most commonly involved (85%), and 50% of untreated patients die within 5 years after the initial infection. Pulmonary Tuberculosis is primarily identified symptomatically using features like cough, fever, sweats, weight loss and hemoptysis and extra-pulmonary lymph node swelling (lymphadenitis)[9]. Also disseminated/miliary TB is characterized by mycobacterial infection apart from lung and lymph node, in any part of the body, including the bone, meninges and kidneys. The probability of developing TB disease is much higher among people living with HIV. It is also higher among people affected by undernutrition, diabetes, smoking and alcohol consumption[10]. The present study was conducted to assess cases of pulmonary tuberculosis.

In present study, out of 238 patients, males were 138 and females were 100. Guler et al[11] evaluated the demographic factors and clinical features of extrapulmonary tuberculosis (EPTB) compared to those of pulmonary tuberculosis (PTB) among adult immunocompetent patients. Among the 427 patients, 55 patients with both PTB and EPTB and who were using steroids or had taken immunosuppressive drugs were excluded from the study. Of the 372 patients, 227 (61%) were males and 168 (45.2%) had EPTB; 204 (54.8%) patients had PTB. The most frequent sites of EPTB were the lymph nodes (n = 45, 12.1%), pleura (n = 40, 10.7%) and brain (n = 7, 1.8%). The most common symptoms were cough (n = 174, 46.7%),

night sweats (n = 127, 34.1%) and fever (n = 123, 33%). Compared to EPTB patients, PTB patients were less likely to have received Bacillus Calmette-Guérin vaccination (odds ratio 0.41, 95% confidence interval 0.2–0.63, p < 0.001). Eighty-one (48.2%) of the EPTB and 146 (71.6%) of the PTB patient.

We observed that <25 years had 110 and 25–40 years had 128 patients. Fever was present in 203, fatigue in 156, weight loss in 82, cough in 118 and hemoptysis in 73 patients. Involved area was lymph nodes such as cervical in 30, inguinal in 54, mediastinum in 28, axillary in 52, paratracheal in 22, omentum in 18, peritoneum in 10, vertebra in 6, wrist in 8, skin in 5 and CNS in 5 cases. Kesete et al[12] assessed the prevalence of tuberculosis disease among patients attending at Nakfa Hospital, Eritrea. A total of 1100 patients were examined for tuberculosis using acid fast staining test. The overall prevalence of smear positive pulmonary TB cases was 7.8% (86 cases out of 1100). Females (8.2%) were more prone to have a positive Tuberculosis smear than males (7.4%). According to severity of infection, 38(3.5%) of subjects were +1 positive, whereas 23(2.1%) and 24(2.2%) of patients were +2 and +3 positives respectively. The highest prevalence of pulmonary TB was observed in the adult age group of 41-60 years (11%) and a comparatively higher number of cases was recorded in age group 21–40 years (8.3%). Adults aged between 41 to 60 had a two times more likelihood to be infected with Tuberculosis than those aged below 20 years old. Moreover, pulmonary tuberculosis was highly prevalent among middle age (20-60) than any other age class in all study years (2014-2019). The pulmonary TB cases were highly predominant during the year 2014 which was 16.8% (19 of 113 subjects) whereas the almost a quarter of it (4.5%) was recorded in following year. Based on locality, the highest rate of infection was observed in Adobha (25%), a town at border of Sudan and Eritrea, in which patients who came from Adobha had 4 times more likelihood to be infected than those from Nakfa town.

Gupta et al[13] evaluated spirometry in cured PTB patients and its association with radiological abnormalities and duration after being cured.75 PTB treated patients (47 males, 28 females) underwent clinico-radiological evaluation, and spirometry [FEV1, FVC, FEV1/FVC ratio]. The patients were further classified into 3 groups according to recent guidelines (ATS/ERS joint statement) i.e mixed, obstructive and restrictive defect. Abnormal PFT was seen in 92% (69/75cases). Mixed pattern was seen in 36%, restrictive defect in 34.7% while obstruction was seen in 21.3% cases. Restrictive abnormality was more commonly seen in females (P=0.030) and old age (P=0.000006) while obstruction in males and young population. Statistically significant direct association of pulmonary impairment was seen with radiological changes (P<0.001) and post treatment duration(P=0.012) but not with age.

Conclusion

Authors found that maximum cases were seen in males and common site was inguinal lymph node.

A Prospective Study on Incidence of Septicaemia in patients in IPD of Medicine Department

K . Sravan Reddy

Assistant Professor, Department of General Medicine, Kanachur Institute of Medical Sciences, Natekal, Mangaluru.

ABSTRACT

Background: *Bloodstream infections are important causes of mortality and morbidity. Rapid empiric antibiotic therapy is often needed. Knowledge of epidemiological data of common pathogens and their antibiotic sensitivity pattern is needed for rapid therapy.*

Methods: *This study was done to analyze the common causes of septicaemia and their antibiotic sensitivity pattern from the Department of General Medicine, Kanachur Institute of Medical Sciences, Natekal, Mangaluru. Isolates were identified using bacteriological and biochemical methods and antibiotic sensitivity was done using the Kirby-Bauer disc diffusion method.*

Results: *This study showed that of the 75 patients examined 22 had septicaemia. 31-45 years age group patients constituted the greatest percentage of infected subjects (n=28) followed by patients aged between 46-60 years (n=17). Gram-positive bacteria were encountered more often than gram negative bacteria. Among the gram positive bacteria, majority isolated were S. epidermidis; followed by S. aureus.*

Conclusion: *Majority of the organism isolated were from Gram positive category, in which S. epidermidis was the most isolated.*

Key words: *Septicaemia, Infection, Emergency coli.*

INTRODUCTION

Septicaemias are important causes of mortality and morbidity and are among the most common healthcare associated infections.[1] Illnesses associated with bloodstream infections range from self-limiting infections to life threatening sepsis that require rapid and aggressive antimicrobial treatment.[2] A wide spectrum of organisms has been described and this spectrum is subject to geographical alteration. Patients who are granulocytopenic or inappropriately treated may have a mortality rate that approaches 100%.[1]

Moreover, fatalities among patients infected with Gram-negative bacilli are higher than those among patients who have Gram-positive cocci as causative agents of their bacteraemia.[3] Worldwide, emergence of antibiotic resistance in all kinds of pathogenic bacteria is a serious public health issue. It is associated with greater hospital mortality and longer duration of hospital stay, thereby increasing health care costs.[4] Also, colonization and infection with antibiotic-resistant bacteria has made the therapeutic options for infection treatment extremely difficult or virtually impossible in some instances.[5] There are many reasons for this alarming phenomenon, including increasing antibiotic use and misuse in humans, animals and agriculture, clustering and overcrowding and poor infection control.[6]

Due to the high mortality and mobility associated with septicaemia, antimicrobial therapy in most cases is initiated empirically before the results of blood culture and antimicrobial susceptibility pattern of the isolates are available.[1]

Knowledge of local antimicrobial resistance patterns from accurate bacteriological records of blood culture results is needed to provide guidance towards an empirical therapy before sensitivity patterns are available. Bacteraemia is usually caused by a wide spectrum of bacteria with varying antimicrobial susceptibility pattern. However, there is a paucity of information about the relative contribution of different bacteria to infections in Sub -Saharan Africa and how this varies across the full range age groups.[7] Bacteraemia often require prompt diagnosis and effective treatment to prevent death and complications from septicaemia. Physical signs and symptoms are usually useful in identifying patients with septicaemia and other non-localized infections but these have limited specificity.[8] Bacteriological culture to isolate the offending pathogen and determine its antimicrobial sensitivity pattern has remained the mainstay of definitive diagnosis of septicaemia.[9] In most cases of suspected septicaemia antimicrobial therapy is always initiated empirically because bacteriological culture results take about a week to be available.

Epidemiological data on common blood stream pathogens and their antimicrobial sensitivity pattern is thus very important to make the right choice of empiric therapy.

METHODS

This study was conducted in the Department of General Medicine, Kanachur Institute of Medical Sciences, Natekal, Mangaluru. All the subjects were patients suspected clinically for septicaemia and sent to the bacteriology laboratory for blood culture by physicians. Written informed consent was taken before the study. The blood culture bottles were immediately incubated aerobically at 35°C for 24 hrs.

After 24hrs, bottles were checked for positive cultures (growth on the agar slope and/or turbidity in the broth). Negative cultures were re-incubated and checked daily for up to three weeks unless growth occurred. Before re-incubation, the slope was re-inoculated by tippling the bottle. Antibiotic susceptibility testing was done on MH using the Kirby-Bauer disc diffusion technique.[11] Antibiogram for Streptococcus species was done on blood agar.

RESULTS

Of the 75 patients examined for septicaemia, positive culture was found in 22 (29.33%). Age distribution of the patients is shown in Table 1.

Majority of the infected patients were found in the 31-45 years of age group (n=28) followed by 46-60 age group (n=17) and least in >76 age group. Maximum no. of positive culture was found in 31-45 age group followed by 46-60 years age group.

The type and pattern of bacteria isolates in the various age groups is shown in Table 2. Gram-positive bacteria were encountered more often than gram negative. Among the gram- positive bacteria, Staphylococci constituted most followed by Streptococci species. Among gram-negative bacteria, enterobacteriacea and non-fermenting bacteria were more frequent.

Table 1. Age Distribution of Patients with Septicaemia

Age ranges (years)	No clinically examined	No (%) of positive culture
15-30	14	3
31-45	28	10
46-60	17	6
61-75	12	2
>76	4	1
Total	75	22

Table 2:- The Type and Distribution Of Bacteria Isolates

Bacteria Isolates	Total
S aureus	5
S. epidermidis	6
S. saprophyticus	1
Streptococcus sp	1
S. typhi	1
Salmonella species	2
K. pneumonia	1
E. coli	1
Enterobacter sp	1
Pseudomonas sp	1
Acinetobacter sp	1
Proteus mirabilis	1
Non enterobacteriacaece	1
Gram positive bacilli	1

DISCUSSION

This study is a record of septicaemia in patients attending the Medicine department of Department of Medicine, Kanachur Institute of Medical Sciences. Results showed that septicaemia was present in 29.33% of patients examined. Gram positive bacteria were encountered more than gram-negative bacteria, and the most frequent invasive bacteria were Staphylococcus epiderimidis, S. aureus, Salmonella typhi and Klebsella species.[6]

These results are similar to those obtained in some previous studies[9]. Bacteremia was identified in 552 (45.9%) of 1201 children in Nigeria; 53.4% of the infections were due to gram positive bacteria and 46.6% due to gram negative bacteria. The most frequent isolate was S. aureus (47.7%) followed by coliforms (23.4%), unidentified gram-negative rods (8.0%), Pseudomonas aeruginosa (5.8%), Streptococcal species (4.7%) and Chromobacteria species (4.5%). Hill et al.[7] also reported an incidence of 34% (297) out of 871patients studied. The isolates were dominated by gram-positive bacteria.

Results have also shown a very high incidence of septicaemia among 31-45 age group. It is also in accordance with results from Laos in which 69.2% of Staphylococci were form majority bulk.[12] The rate of isolation also reduced with increasing age as seen in this study.

However, while this study represents real life clinical practice in the hospital in which it was conducted, our approach had some limitations.

The primary reason for requesting the blood culture from patients is still not clear.

CONCLUSION

This study shows that *Staphylococcus epidermidis*, *S. aureus* and *Salmonella typhi* are the living cause of bacteraemia among patients in the locality.

Effect of Cigarette Smoking on Male Fertility : A Prospective Hospital Based Study

K. Sravan Reddy

Assistant Professor, Department of General Medicine, Kanachur Institute of Medical Sciences, Natekal, Mangaluru

ABSTRACT

Background: *World Health Organization (WHO) has reported that smoking is very much prevalent among 30% of all 15 years and older men. Approximately 46% of smokers (men) belong to reproductive age (20 - 39 years of age). A survey from 187 countries reported that the prevalence of smoking in male smokers was decreased from 41.2% in 1980 to 31.1% in 2012. Though, the number of everyday smokers increased from 721 million in 1980 to 967 million in 2012.*

Methods: *Eighty male cases were included in this study. Out of eighty male cases 51 had low sperm count & 29 cases were normal. The study was conducted in Department of General Medicine, Kanachur Institute of Medical Sciences, Natekal.*

Results: *In the present study, low sperm count was occurred in 36.3% and normal sperm count was occurred in 63.7% cases.*

Conclusion: *The results of the present study showed that smoking has severe effects on male fertility. It decreased the sperm motility and sperm count and causes a further decline with continuation of smoking for more than five years.*

INTRODUCTION

It is a well-known fact that smoking has a harmful effect on health in general and on male reproductive system in particular. Despite that it remains a worldwide phenomenon.[1] World Health Organization (WHO) has reported that smoking is very much prevalent among 30% of all 15 years and older men.[2] Approximately 46% of smokers (men) belong to reproductive age (20 - 39 years of age).[3] A survey from 187 countries reported that the prevalence of smoking in male smokers was decreased from 41.2% in 1980 to 31.1% in 2012. Though, the number of everyday smokers increased from 721 million in 1980 to 967 million in 2012.[4]

Semen quality is supposed to be informative about male fertility, that is defined biologic capacity of males for reproduction.[5] Semen analysis is the clinical standard for assessing male fecundity.[6] Apart from this, sperm concentration, motility and morphology are reported to be the key components of classifying men by fertility potential.[7] Infertility is defined as the inability to conceive after twelve months of regular sexual relation without the use of contraception.[8] It poses severe consequences at the cultural, social and emotional levels. It leads to distress, anxiety, blame and sexual problems in married couples' lives.[9]

Tobacco has numerous carcinogens and mutagens which have deadly effects on human beings. One of the most harmful effects of carcinogens has been observed to be more on rapidly dividing cells that include germ cells. It has been

Source of Support: Nil, Conflict of Interest: None

already reported that the prevalence of smoking is very much high in young adult males in the reproductive period. Despite this, the undesirable effects of smoking are not well recognized and its impact on male fertility and sperm characteristics still remains debatable.

METHODS

Study Population: - Eighty male cases were included in this study. Out of eighty male cases 51 had low sperm count & 29 cases were normal.

Study Area: -The study was conducted in the Department of General Medicine, Kanachur Institute of Medical Sciences, Natekal

Sample Collection: - In this study 13 non-smokers and 67 smokers in the age group between 25 to 40 years attending the primary infertility clinic who smoked a minimum of 10 cigarettes per day. They were categorized on the basis of duration of smoking as those smoking cigarettes for less than 5 years or for more than 5 years

Data analysis:-Data were analyzed by using of Microsoft Excel.

RESULTS

In our study, 80 total numbers of cases were included in this study. Among the 80 cases 13 belongs to non-smoking and 67 were belongs to smoking history. In the present study, low sperm count was occurred in 36.3% and normal sperm count was occurred in 63.7% cases. On the basis of above result the present study is undertaken to observe the effects of smoking on a few selected seminal fluid parameters like sperm count and motility and to compare the results.

Table 1:- Smoking & non-smoking history in all cases

Smoking history	No. of cases	Percentage
Non-smokers	13	16.3%
Less than 5 years	27	33.7%
More than 5 years	40	50%
Total	80	100%

Table 2:- Distribution of cases according to sperm count

Motility	Frequency	Percentage
Normal (greater than 32%)	29	36.3%
Low (Less than 32%)	51	63.7%
Total	80	100%

Table 3:- Comparative study between non-smoker & smoker and sperm motility

Smoking history	Sperm motility greater than 32%		Sperm motility less than 32%		Total
	No of cases	Percentage	No of cases	Percentage	
Non-smokers	10	76.9%	3	23.1%	13
Smokers less than 5 years	12	44.5%	15	55.6%	27
Smokers greater than 5 years	7	17.5%	33	82.5%	40

DISCUSSION

It has been observed in many studies that the effects of cigarette smoking on all the seminal parameters are detrimental. Though, its effect on the individual parameters is yet to be established. Due to smoking, there is an increase in the concentrations of reactive oxygen species and cadmium which affect sperm quality.[10] A good primary testicular function may compensate the free radical injuries. As, this is known that sperm count is used to measure the effectiveness of spermatogenesis. Epididymal maturation and sperm functional capability are indicated by sperm motility.[11] Sperm motility is attributed to its tail which is composed of flagella. The mid piece provides the required energy for the movement which is rich in mitochondria.[12] Motility is important for the normal functioning of sperm, as it is not only helpful in transportation but also in penetrating the outer layers of ovum for fertilization.[13] Hence, the sperm motility can be considered as the most important factor that influences fertility.

It has been revealed in the previous researches that mammalian sperm remain motile in the female genital tract and free energy released from the hydrolysis of ATP that is required for this movement.[14] Zavos et al., have reported that abnormalities in the ultrastructure of the flagellum and the axonemal structures of the sperm tail are related with reductions in sperm motility.[15] Garrett et al., have observed in their study that superior sperm morphology and motility increased the pregnancy rates.[16]

The present study results found decreased sperm motility and sperm count in cigarette smokers with a smoking history of more than 5 years. Out of the 80 subjects, 51 subjects had low sperm count. It showed that the sperm count was less affected than the sperm motility. Zakarya Bani Meri et al., revealed in one of their study that sperm concentration was less among heavy smokers as compared to the light smokers. They concluded that, cigarette smoking has a harmful effect on some of the seminal fluid parameters like motility, morphology and leukocyte count that result in male subfertility.[17] Farkhunda Nadeem et al., found the potential dangerous chemicals present in cigarette smoke which may affect chromosomes and lead to sperm abnormality. They also reported that smoking can decrease the sperm motility and percentage of normal sperm cells that results male infertility. It is also correlated with the number of cigarettes smoked per day.[18] These results supports our study and many other studies also (Shaaraway M et al., Vytas Kaulikauskas et al., Vogt et al., Hughes ED et al, Vine MF et al., Alexander E et al., Al Bader A et al., S. Sinclaire, Arabi M and Somwanshi et al.).[19–28] Azar Aghamohammadi et al. revealed some contradictory results to our study that there was no significant difference in sperm quality in smokers except for semen volume and total sperm count. Though, they also concluded that quitting smoking is beneficial for enhancing general health. So, more research is necessary to evaluate its role in male fertility.[29]

CONCLUSION

The results of the present study showed that smoking has severe effects on male fertility. It decreased the sperm motility and sperm count and causes a further decline with continuation of smoking for more than five years.

ABSTRACT

Background: The use of central venous catheters (CVCs) has greatly improved the quality-of-care in cancer patients, yet these catheters may cause serious infectious and thrombotic complications. The aim of this retrospective study was to study the various types of CVCs and their complications. **Materials and Methods:** We studied retrospectively 213 cases of CVCs in our institute with their indications, type and complications from August 2010 to July 2011. **Results:** A total of 213 CVCs were inserted in patients with hematological (62%) and solid organ malignancies (38%). Ninety-eight patients (46%) had peripheral inserted central catheter (PICC), 90 (42%) patients had Hickman catheters and 25 (12%) had a port. The median duration of retention of Hickman catheters was 104 days (3-365 days), for the peripherally inserted central catheters was 59 days (3-100 days) and for the port it was 280 days (45-365 days). Non-infective complications were more than infective (12% vs. 7%). The most common complication was non-infective occlusion and thrombophlebitis. In one patient with PICC thrombosis occurred in the cephalic, radial and ulnar vein and in one patient with port thrombosis occurred in the superior vena cava. Organisms were isolated in 80% (12 out of 20) of cultures. Common organisms isolated were *Pseudomonas aeruginosa* in 5 (42%), *Staphylococcus aureus* in 2 (16%), *Escherichia coli* in 2 (16%) and *Aspergillus* in 3 (25%) patients. 7 out of 12 infected patients had negative blood cultures within 7 days of antibiotic treatment. 5 patients remained positive for more than 7 days with antibiotics. In 165 patients (73%), the desired treatment protocol was completed and at present there are still 28 patients (13%) with catheters. 5 patients (2.3%) died of febrile neutropenia and septicemia with multi-organ failure. In 5 patients (2.3%), the catheters (1 Port, 1 Hickman and 3 PICC) were prematurely removed because of thrombosis. **Conclusion:** CVCs are better options to facilitate the long-term vascular access provided infection is prevented with meticulous care and treated promptly with proper antibiotics. Most CVCs is acceptable to patients.

Key words: *Central venous catheter, chemo port, Hickman central venous catheter, peripheral inserted central catheter*

INTRODUCTION

Cancer patients require frequent intravenous administration of chemotherapy, antibiotics, blood components, etc., for a considerable period of time. Repeated venipunctures are poorly tolerated by these patients. The introduction of central venous catheters (CVCs) in the 1980s significantly improved the quality-of-life of oncology patients.[1,2] However, the use of these CVCs has been associated with mechanical, infectious and thrombotic complications.

Central venous devices are of various types like open-ended tunnelled catheters, tunnelled valve catheters and implanted subcutaneous ports, non-tunneled external catheters (CVCs and peripheral inserted central catheters (PICCs)).

Relative contraindications are bleeding disorders, anticoagulation or thrombolytic therapy, combative patients, distorted local anatomy, cellulitis, burns, severe dermatitis and vasculitis.

Selection of the device is based on the number of factors such as disease, number and type of solutions, osmolality,

flow required and duration of use- days versus months, preference of physician and patient and cost of the device.

Complications are acute or delayed. Acute are: (1) procedure related; Dysrhythmias, catheter knotting or malposition, nerve injury, pneumothorax, hemothorax, hydrothorax, hemomediastinum; (2) vascular: Air embolus, arterial puncture, arteriovenous fistula, hematoma, blood clot; (3) infectious: sepsis, cellulitis, osteomyelitis, septic arthritis. Delayed like postinsertion phlebitis, extrinsic compression, i.e., pinch off, kink, catheter occlusion by precipitate, thrombus, fragmentation and infection.

AIMS AND OBJECTIVES

Aims

To study the profile of patients with CVCs and types of CVCs with respect to their complications.

Objectives

- Indications for various types of CVCs.
- Complications and their management overview.

MATERIALS AND METHODS

A retrospective study of function and complication rates of CVCs ($n = 213$) placed in children (112) and adults (101) at our institute over a 1 year period (August 2010 till July 2011) was done. We retrieved case files from the medical record department and reviewed for demographic profile, indication of insertion, any immediate, acute and late-onset complications. Indications of removal of catheter such as infection, occlusion and completion of treatment were noted.

Study population

Patients who were admitted to medical and pediatric oncology department underwent catheterization for various purposes were studied. The CVCs used were peripherally PICC, Hickman CVC (HC) or a chemo port (CP). A total of 458 CVCs were inserted. Patients with short-term catheter cavafix and subclavian/internal jugular vein (IJV) certofix (145) were excluded from the study. Patient with incomplete data (101) regarding CVC removal, lost to follow-up and catheter insertion outside the Gujarat Cancer Research Institute (GCRI) were also excluded from the study.

RESULTS AND ANALYSIS

In our study, median age of pediatric patients was 4 year (6 month to 14 year) and for adults 40 years (>14-65 year). The 112 (52.6%) CVCs were inserted in pediatric patients and 101 (47.4%) were in adult patients. Hickman was preferred in pediatric group, out of 112 CVCs, 68 (61%) were Hickman, 32 (28%) were PICC and 12 (11%) were port. Although in adults PICC was commonly used. Out of 101 CVCs, 66 (65%) were PICC, 22 (22%) were Hickman and 13 (13%) were port [Figures 1, 2, and Table 1].

Overall 62% CVCs were used in hematological malignancies and 38% were used in solid malignancies. In pediatric patients, acute lymphoblastic leukemia was most common indication others were Ewing sarcoma, rhabdomyosarcoma, retinoblastoma, hepatoblastoma, neuroblastoma, wilms' tumor and germ cell tumor. In adults most common indication was acute myeloblastic leukemia, others were breast cancer, colorectal cancer, head and neck cancer and non-Hodgkin's lymphoma.

Overall median duration of CVCs was 89 days, for PICC 59 days, Hickman catheter 104 days and for port it was 280 days.

Catheter related complications were seen in 40 (19%) CVCs. Non-infective complications (12%) such as thrombophlebitis, malposition, swelling and occlusion were more common than infective (7%).

Blood cultures and/or catheter tip cultures were send in 20 cases. Organisms were cultured in 12 (60%) specimens. Most common organism was *Pseudomonas* (five cases) while *Aspergillus* (3), *Staphylococcus aureus* (2) and *Escherichia coli* (2) were found in others. 7 out of 12 infected patients had negative blood cultures within 7 days of antibiotic treatment while 5 patients remained positive. In 155 patients (73%), the desired treatment protocol was completed and at present there are still 28 patients (13%) with catheters. 5 patients (2.3%) died of febrile neutropenia and septicemia with multi-organ failure. In 5 patients (2.3%), the catheters (1 Port, 1 Hickman and 3 PICC) were prematurely removed because of thrombosis.

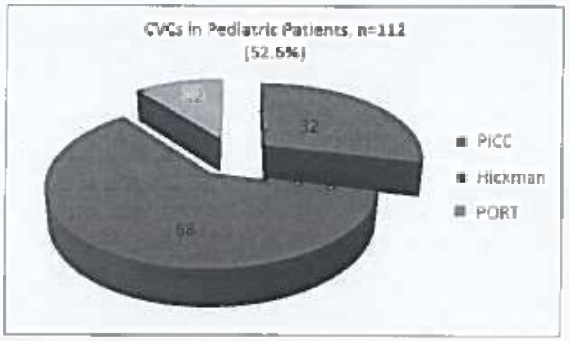

Figure 1: Number of pediatric patients with different central venous catheters

DISCUSSION

CVCs have a paramount role throughout the management of cancer patients, as they are needed in the initial phases for surgery or chemotherapy, in the advanced stage for chronic treatment and in the last stage for palliative measures. Central venous access is commonly attempted in the IJV, subclavian vein, femoral vein or arm veins.[3]

Physicians must determine the individualized catheter type by considering various factors such as catheter duration, technique, compliance, complications, cost and efficacy. CVCs are classified by tip position, technical features or materials. They can be classified in terms of short-term, medium-term or long-term access. Because superior vena cavas (SVCs) are a non-tunneled catheter, the expected duration was generally short and they have a known disadvantage of infection. The PICC is also a non-tunneled catheter and is useful for a relatively longer duration. The CP is a tunneled catheter and is useful for the long term. Tunneled catheters and PICCs[4,5] and are held to have lower infection rates, but no randomized controlled trials have demonstrated this contention to date.[6] Additionally, thrombosis occurs more often with a PICCs than other catheters due to the influence of multifactorial phenomenon.[7]

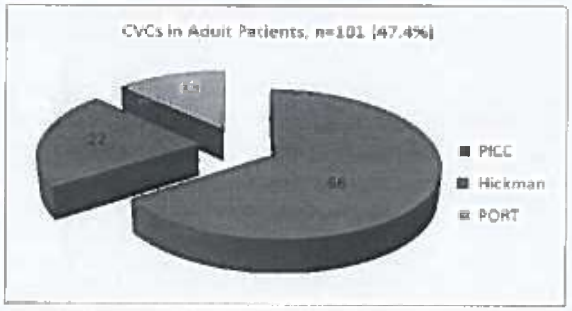

Figure 2: Number of adult patients with different central venous catheters

Table 1: Patient data

Total no. of patient	213
Median age	
Pediatric	4 years (6 months to 14 years)
Adult	40 years (>14-65 years)
Indication (%)	
Solid malignancy	81 (38)
Hematological malignancy	132 (62)

Table 2: Median duration of different devices

Median duration		
Types	Range (days)	Median (days)
PICC	3-200	59
Hickman	3-365	104
Port	45-365	280
All	3-365	89

PICC - Peripheral inserted central catheter

The incidence of catheter related complication was 19% in our study with 12% non-infected such as occlusion, malposition and swelling while 7% infected. In the study by Kim,[8] they had 18.3% non-infected complication like malposition, thrombosis, bleeding and 12.8% infected complications. In a prospective study by Nirni,[9] infection was found in 30% of cases with 26% culture positive, mainly for *S. aureus*. Jain *et al*.[10] found infection in 16% cases. In the study by Winter *et al*.[11] 13% had a non-infective complication while only 1% had infective complication. The incidence of documented thrombosis was 2.3% in our study, which was relatively low despite not using prophylactic anticoagulation. One patient with acute myeloid leukemia (AML) developed thrombosis in the cephalic, radial and ulnar vein (PICC). Other two patients with PICC thrombosis were AML induction (1) and acute lymphocytic leukemia (ALL) consolidation (1). While one patient with ca breast on adjuvant chemotherapy developed thrombosis in SVC (Port) and another patient with ALL consolidation developed thrombosis in HC. The thrombosis incidence rate tended to be more frequent (three cases) in patients with PICCs than Hickman and CPs. Nirni and Kim *et al.* noticed 2% and 4.5% incidence of thrombosis in their studies respectively. In our study incidence of complications are less, probably secondary to proper counselling, strict aseptic precautions and proper cath flush. Furthermore, we have separate CVC care service and dedicated nursing staff.

We found one catheter-related immediate-onset complication in AML induction patient in the form of hemothorax after IJV insertion, that patient also had PICC related thrombosis and pulmonary embolism and was expired. No other immediate complication like pneumothorax, except bleeding was found. Most cases were performed by an expert anesthetist or by expert oncology resident. Majority of PICC insertion were without using ultrasound (USG) or fluoroscopic guidance. A study has also reported that USG is not beneficial for reducing catheter-related complication.[12] However, it is optimal to insert catheters using USG or fluoroscopic guidance if facility available to reduce the immediate-onset complication rate.

The median PICC life span was 59 days (3-100 days), for Hickman 104 days (3-365 days) and for port 280 days (45-365 days). Overall median duration was 89 days until study completed. In addition, a longer-term use of catheters occurred in patients with a solid malignancy than hematologic malignancy. Patients with a solid malignancy underwent a CP rather than another catheter type due to scheduled, intermittent long-term chemotherapy. Therefore, the CP was considered an

Table 3: Comparison of different studies

Author	Median duration (days)	Non-infected %	Thrombosis %	Infection %	Culture positivity %	Organism
Nirni *et al.* (*n*=50)	84	11	1	30	26	*S. aureus*
Jatin *et al.* (*n*=52)	90	5.6	NA	16	NA	*S. aureus*
Winter *et al.* (*n*=43)	153	13	NA	1	NA	NA
Kim *et al.* (*n*=219)	46	18.3	4.5	32.8	NA	NA
Present study (GCRI) (*n*=213)	89	12	2.3	7	40	*Pseudomonas*

S. aureus=*Staphylococcus aureus*; GCRI=Gujarat Cancer Research Institute

effective tool for long-term use in patients with cancer. In Kim study, the median catheter life span was 46 days and the CP was useful for the long term (median 269 days); however, the median life span of the PICC was 37 days. In studies by Nirni, Jatin *et al.* and Winter *et al.* had median duration of 84 days, 90 days and 153 days respectively.

CONCLUSION

CVCs are better options to facilitate the long term vascular access provided infection is prevented with meticulous care and treated promptly with proper antibiotics. Most CVCs are acceptable to patients.

The major problems related to CVCs were thrombosis, malposition or migration of the tip and infection. Port is an effective tool for long-term use in patients with cancer, while Hickman and PICC are feasible for few months. In addition, the insertion of CVCs with the image guidance is advisable and the fixation of the tip is important for the management of PICC.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Bharat J. Parikh (MD, Professor and Chief of Medical Oncology Unit 1, Gujarat Cancer and Research Institute, Ahmedabad), Dr. Asha N Anand (MD, professor Deparment of Medical and Pediatric Oncology, Gujarat Cancer and Research Institute, Ahmedabad), nursing staff and patients of Gujarat Cancer and Research Institute.

DOI: https://doi.org/10.21276/iabcr.2019.5.4.13

Keywords: Acute myocardial infraction, Uric acid, STEMI

Abstract

Background: *Higher levels of SUA are also associated with hypertension and renal disease. It is observed in >75% of patients with malignant hypertension. This elevation has been reported as a result of decreased renal blood flow and resultant increased urate reabsorption. It has been further reported that a 1 mg/dL increase in SUA levels was associated with a 26% increase in mortality.*

Methods: *. The duration of study was over a period of two year. Total 204 cases were included with acute myocardial infraction. This study was conducted in the Department of Medicine.*

Results: *In this study 204 cases of acute myocardial infraction were included. Among all cases 132 were male & 72 were female. Prevalence of uric acid level in acute MI cases were 4.1-5.5 mg/dl seen in 28.4% followed by >7.0 mg/dl in 27.4%, <4 mg/dl in 22.5% & 5.6-7.0 mg/dl in 21.5%.*

Conclusions: This study concludes that serum uric acid is a cheap and effective prognostic indicator of AMI.

ABSTRACT

Background: *The present study was attempted for multivariate analysis through principal component analysis for carotid intima medial thickness (CIMT) as dependent variable compared to different independent variables used as parameters in diabetes and dyslipidaemia. Invasive mechanical ventilation (MV) should have to be used commonly to stabilize and treat critically ill patients in an ICU. Iatrogenic lung damages, including VAP, have been reported as some hazards of MV. These hazards are affected by the severity of illness, duration of MV, immunity and physiological reserve of the individual.*

Methods: *The biochemical and obese data of total 75 patients were taken from earlier study. The data of six biochemical markers of DM and dyslipidaemia along with one obese marker and CIMT were analysed. Data were analysed for Pearson's-Spearman correlation coefficients matrix for the relationships between CIMT and parameters of DM as well as dyslipidaemia. Principal component analysis (PCA) was performed to reduce the variables into a smaller number of uncorrelated predictor variables. Individual PC scores were generated from their risk factors loadings for DM and dyslipidaemia separately. The duration of study was over a period of one year. This study was conducted in the Department of Medicine. The study was over a period of one year and it was separated into a 6 month for pre-implementation period throughout which standard care used for mechanically ventilated cases and a for the post-implementation period also 6 months included throughout which a VAP care bundle was affected.*

Results: *In our study 323 & 306 cases were required >48 hrs during Pre-implementation period & during Post-implementation period respectively. Different types of microorganism we isolated from all cases.*

Conclusions: *It can be concluding that constant compliance with quality improvement practices would reduce the incidence of VAP shortly.*

Keywords: *VAP, Micro-Organisms, Nosocomial pneumonia*

INTRODUCTION

Nosocomial pneumonia is one of the most acquired infections in the intensive care unit (ICU). In a number of cases, the patient's critical condition and causal disease need invasive procedures and diagnostics, which may instigate the risk of colonization by the exogenous microbes.[1-3] Endotracheal intubation is one of the most used invasive procedures. An artificial respiratory tract eliminates the physiological functions like heating, humidification and purification of the upper respiratory mucosa and increase the risk of ventilator-associated PNEU (VAP).[4-7] The microorganisms of VAP and their varied drug resistance among different hospitals wards[8] incite a need for local surveillance data that is extremely essential in starting local procedures for PNEU prevention.[1,9,10] Though the lower respiratory tract samples are the best to diagnose causative microorganism of VAP, the invasive sampling is not possible, every time.

Invasive mechanical ventilation (MV) should have to be used commonly to stabilize and treat critically ill patients in an ICU.

Iatrogenic lung damages, including VAP, have been reported as some hazards of MV. These hazards are affected by the severity of illness, duration of MV, immunity and physiological reserve of the individual.[11,12] Patients diagnosed with VAP have been found to have a longer ICU stay,[13] higher mortality rates[14] and excessively inflated costs of treatment.[15]

It has been reported that the mortality rates in intubated ICU patients were higher than the patients who do not need ventilator support . It has been reported that in ICU patients, VAP developed 2–3 days after the endotracheal intubation. To diagnose VAP earliest, ICU care specialists should be alarmed for infection alerts (e.g. fever, white blood cell count change) and at new or progressive radiological infiltrate, altered sputum characters and isolation of a causative organism.[15]

METHODS

Study duration: - The duration of study was over a period of one year.

Study Area:-This study was conducted in the Department of Medicine.

Data Collection:-

The study was over a period of one year and it was separated into a 6 month for pre-implementation period throughout which standard care used for mechanically ventilated cases and a for the post-implementation period also 6 month included throughout which a VAP care bundle was effected. All adult patients were recruited in the study. In our study we were included who were above 18 years of age, intubated and mechanically ventilated cases. Those cases intubated prior to admission to the ICU, ICU length of stay less than 48 hours, and tracheostomies cases were excluded in this study.

Data Analysis:- Data were analyzed by using Microsoft excel.

RESULTS

In our study 739 & 649 cases included during mechanically ventilated cases during Pre-implementation period & mechanically ventilated cases during Post-implementation period respectively. Among all 323 & 306 cases were required >48 hrs during Pre-implementation period & during Post-implementation period respectively. In Pre-implementation cases 59% male & 41% were female. While 63% cases were male during Pre-implementation & 37% were female during post implementation period. 29 VAP cases pre-implementation cases & 12 post-implementation cases were microbiologically confirmed. Different types of microorganism were isolated which showed in table 6.

Table 1: Distribution of cases according to implementation period

Pseudomonas spp	4	3
Fungal	3	2
Total	29	12

DISCUSSION

It has been reported in various studies that several studies have shown that the involvement of a multidisciplinary team led to a decrease in nosocomial infections and VAP.[16,17] In the present study, a VAP prevention bundle containing five elements; 30° head-up position, daily mouth wash with chlorhexidine gel (2%), continuous aspiration of subglottic secretions, daily sedation review, and daily assessment for weaning and extubation was used. This bundle was first described by the Scottish Intensive Care Society Audit Group for the Scottish Patient Safety Programme.[18] It was found in the present study that the use of a VAP prevention bundle caused a substantial decrease in the incidence of VAP. Findings of Wip and Napolitano[19] study supported the findings of the present study.

In the present study, peptic ulcer prophylaxis or DVT prophylaxis was not included in the VAP bundle as these were part of our standard regimen for critically ill patients' management. It has been reported in a couple of studies that the gastric reflux and aspiration of the gastric contents were commonly seen in supine patients while receiving enteral nutrition.[20,21] This was prevented with a semi-upright position of patients on mechanical ventilation.[22-24] This has been reported earlier that the patients in a 30° head-up position have fewer chances of developing VAP in comparison to patients positioned at less than 30°.[25,26] A decrease in the incidence of early VAP has been reported by using a subglottic secretion ETT 31 and the CASS endotracheal tube.[27,28]

It has been found that the excessive use of sedation in the ICU resulted in various side effects such as gastrointestinal motility disturbances and difficult weaning from the MV. On the contrary, it has been found in another study that the use of the least amount of sedation decreased the number of ventilated days and ICU mortality and early extubation associated with shorter duration of MV. Therefore, daily sedation interruptions of all the intubated patients have been suggested previously, if their clinical condition allows.[29-31] Prolonged intubations have been further reported to increase the chances of infection, micro-aspiration, gastrointestinal motility, and microcirculatory disturbances.[32,33] A shortened time of MV and reduced duration of ETT exposure has been reported to decrease the chances of aspiration of contaminated secretions and the risk of developing VAP.[34]

CONCLUSION

With the help of the findings of the present study, it can be suggested that the use of a VAP care bundle was an effective regimen for lowering the VAP incidence in different ICUs. It can be further stated that constant compliance with quality improvement practices would reduce the incidence of VAP shortly.

Prevalence of Septicaemia in Patients Admitted in Medicine Department Of a Tertiary Care Hospital

J K Chhaparwal[1], Navendra K Gupta[2*]

[1]Associate Professor, [2*]Assistant Professor, Department of Medicine,
Ananta Institute of Medical Science and Research Center, Rajsamand, Rajasthan, India.

ABSTRACT

Background: Bloodstream infections are important causes of mortality and morbidity. Rapid empiric antibiotic therapy is often needed. Knowledge of epidemiological data of common pathogens and their antibiotic sensitivity pattern is needed for rapid therapy.

Methods: This study was done to analyze the common causes of septicaemia and their antibiotic sensitivity pattern from the Department of Medicine, Ananta Institute of Medical Science and Research Center, Rajsamand. Isolates were identified using bacteriological and biochemical methods and antibiotic sensitivity was done using the Kirby-Bauer disc diffusion method.

Results: This study showed that of the 145 patients examined 40 (27.58%) had septicaemia. 31-45 years age group patients constituted the greatest percentage of infected subjects (n=55) followed by patients aged between 46-60 years (n=38). Gram-positive bacteria were encountered more often than gram negative bacteria. Among the gram-positive bacteria, majority isolated were *S. epidermidis*; followed by *S. aureus*.

Conclusion: Majority of the organism isolated were from Gram positive category, in which *S. epidermidis* was the most isolated.

Keywords: Septicaemia, Infection, Emergency.

INTRODUCTION

Septicaemias are important causes of mortality and morbidity and are among the most common healthcare associated infections.[1] Illnesses associated with bloodstream infections range from self-limiting infections to life threatening sepsis that require rapid and aggressive antimicrobial treatment.[2] A wide spectrum of organisms has been described and this spectrum is subject to geographical alteration. Patients who are granulocytopenic or inappropriately treated may have a mortality rate that approaches 100%.[1] Moreover, fatalities among patients infected with Gram-negative bacilli are higher than those among patients who have Gram-positive cocci as causative agents of their bacteraemia.[3] Worldwide, emergence of antibiotic resistance in all kinds of pathogenic bacteria is a serious public health issue. It is associated with greater hospital mortality and longer duration of hospital stay, thereby increasing health care costs.[4] Also, colonization and infection with antibiotic-resistant bacteria has made the therapeutic options for infection treatment extremely difficult or virtually impossible in some instances.[5] There are many reasons for this alarming phenomenon, including increasing antibiotic use and misuse in humans, animals and agriculture, clustering and overcrowding and poor infection control.[6]

Due to the high mortality and mobility associated with septicaemia, antimicrobial therapy in most cases is initiated empirically before the results of blood culture and antimicrobial susceptibility pattern of the isolates are available.[1]

Knowledge of local antimicrobial resistance patterns from accurate bacteriological records of blood culture results is needed to provide guidance towards an empirical therapy before sensitivity patterns are available. Bacteraemia is usually caused by a wide spectrum of bacteria with varying antimicrobial susceptibility pattern.[7]

Bacteraemia often require prompt diagnosis and effective treatment to prevent death and complications from septicaemia. Physical signs and symptoms are usually useful in identifying patients with septicaemia and other non-localized infections but these have limited specificity.[8]

Bacteriological culture to isolate the offending pathogen and determine its antimicrobial sensitivity pattern has remained the mainstay of definitive diagnosis of septicaemia.[8] In most cases of suspected septicaemia antimicrobial therapy is always initiated empirically because bacteriological culture results take about a week to be available.

Epidemiological data on common blood stream pathogens and their antimicrobial sensitivity pattern is thus very important to make the right choice of empiric therapy.

MATERIALS AND METHODS

This study was conducted in the Department of Medicine, Ananta Institute of Medical Science and Research Center, Rajsamand. All the subjects were patients suspected clinically for septicaemia and sent to the bacteriology laboratory for blood culture by physicians. Written informed consent was taken before the study. The blood culture bottles were immediately incubated aerobically at 35°c for 24 hrs.

After 24hrs. bottles were checked for positive cultures (growth on the agar slope and/or turbidity in the broth). Negative cultures were reincubated and checked daily for up to three weeks unless growth occurred. Before re-incubation, the slope was re-inoculated by tippling the bottle.

Antibiotic susceptibility testing was done on MH using the Kirby-Bauer disc diffusion technique.[11] Antibiogram for Streptococcus species was done on blood agar.

Table 1: Age Distribution of Patients with Septicaemia

Age ranges (years)	No clinically examined	No (%) of positive culture
15-30	22	6
31-45	55	16
46-60	38	12
61-75	25	5
>76	5	1
Total	145	40

Table 2: The Type and Distribution Of Bacteria Isolates

Bacteria Isolates	Total
S.aureus	10
S. epidermidis	12
S. sapropihyticus	1
Streptococcus sp.	2
S. typhi	2
Salmonella species	2
K. pneumonia	2
E. coli	1
Enterobacter sp.	2
Pseudomonas sp.	1
Acinectobacter sp.	1
Proteus mirabilis	1
Non enterobacteriacaece	1
Gram positive bacilli	1
Klebsellla oxytoca	1
Total	40

RESULTS

Of the 145 patients examined for septicaemia, positive culture was found in 40 (27.58%). Age distribution of the patients is shown in Table 1.

Majority of the infected patients were found in the 31-45 years of age group (n=55) followed by 46-60 age group (n=38) and least in >76 age group. Maximum no. of positive culture was found in 31-45 age group followed by 46-60 years age group.

The type and pattern of bacteria isolates in the various age groups is shown in **Table 2**. Gram-positive bacteria were encountered more often than gram negative. Among the gram- positive bacteria, Staphylococci constituted most followed by Streptococci species. Among gram-negative bacteria, enterobacteriacea and non-fermenting bacteria were more frequent.

DISCUSSION

This study is a record of septicaemia in patients attending the Medicine department of Department of Medicine, Ananta Institute of Medical Science and Research Center, Rajsamand. Results showed that septicaemia was present in 27.58% of patients examined. Gram positive bacteria were encountered more than gram-negative bacteria, and the most frequent invasive bacteria were Staphylococcus epidermidis, S. aureus, Salmonella typhi and Klebsella species.[6]

These results are similar to those obtained in some previous studies[5]: Bacteremia was identified in 552 (45.9%) of 1201 children in Nigeria; 53.4% of the infections were due to gram positive bacteria and 46.6% due to gram negative bacteria. The most frequent isolate was S. aureus (47.7%) followed by coliforms (23.4%), unidentified gram-negative rods (8.0%), Pseudomonas aeruginosa (5.8%), Streptococcal species (4.7%) and Chromobacteria species (4.5%). Hill et al.[7] also reported an incidence of 34% (297) out of 871patients studied. The isolates were dominated by gram-positive bacteria.

Results have also shown a very high incidence of septicaemia among 31-45 age group. It is also in accordance with results from Laos in which 89.2% of Staphylococci were form majority bulk.[12] The rate of isolation also reduced with increasing age as seen in this study. However, while this study represents real life clinical practice in the hospital in which it was conducted, our approach had some limitations. The primary reason for requesting the blood culture from patients is still not clear.

CONCLUSION

This study shows that *Staphylococcus epidermidis*, *S. aureus* and *Salmonella typhi* are the living cause of bacteraemia among patients in the locality.

Use of Antihypertensive Drugs in Type 2 Diabetic Patients: A Hospital Based Study

J K Chhaparwal[1], Navendra K Gupta[2*]

[1]Associate Professor, [2*]Assistant Professor, Department of Medicine,
Ananta Institute of Medical Science and Research Center, Rajsamand, Rajasthan, India.

ABSTRACT

Background: Patients with diabetes has 2 fold higher chances of suffering from hypertension. Hypertension is risk factor for development of diabetes as well for complications like nephropathy, CAD and neuropathy etc. Hypertension control is vital to prevent and retard progression of microvascular and macrovascular complications. Therefore, we undertook this study to evaluate treatment patterns in diabetic patients with hypertension, those are being followed at our institute.

Methods: This study was conducted on diabetic patients who had hypertension as well. Prescribing Pattern of Antihypertensive drugs was analysed on all diabetic patients reporting to medicine OPD at Department of Medicine, Ananta Institute of Medical Science and Research Center, Rajsamand were screened.

Results: Out of n=220 patients, 120 were males and 100 were females. Mean age of group was 46.75 years. 46.18% patients were on monotherapy and remaining patients were on combination antihypertensive drugs. There were total 486 antihypertensive drug exposures. Patient needed mean antihypertensive drug of 1.98. Angiotensin receptor blockers were the most commonly prescribed drugs. Angiotensin inhibitors (angiotensin receptor blockers and ACE inhibitors) were utilized in 71 % patients. Hypertension control was achieved in 37.66% patients. About 81.2%) aware about disease.

Conclusion: Our study showed that majority of diabetic hypertensive patients needed multiple drug therapy to control hypertension. Most of the patients were on ARBs/ACE inhibitors. This was according to recommendation by ADA or JNC8.

INTRODUCTION

Hypertension and Diabetes are life style disease and are the major burden of global Health due to complications. India currently has 40.9 million diabetic patients and it is expected to rise to is expected to rise to 69.9 million by 2025 unless urgent and effective preventive steps are taken.[1]

One and half billion people will suffer from hypertension[2] and 300 million will suffer from diabetes by 2025.[3] Prevalence of hypertension is 60% in type 2 DM.[4] Patients with T2DM has two fold higher chances of suffering from hypertension in comparison to age match subjects without diabetes.[5] Hypertension has been shown as a major risk factor not only for the development of diabetes but also for the development of micro and macro vascular complications like neuropathy, nephropathy, retinopathy, coronary artery disease, stroke, Peripheral Vascular Disease (PVD) in diabetic patients. The benefits of Blood Pressure (BP) control in diabetic patients exceed the benefits of tight glycemic control and vital to the prevent and retard progression of both microvascular and macrovascular complications of hyperglycemias.[6]

Therefore, all of the hypertension management guidelines, that is, eighth report of Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure-2013 (JNC-8),[7] American Diabetes association (ADA) 2014[8] and European Society of Hypertension (ESH 2013)[9] focused aggressively on Blood Pressure (BP) control in diabetic patient to below 140/80-90 mmHg.

JNC 8 recommended target of diastolic BP <90 mmHg and ESC 2013 recommended <85 mmHg. But ADA recommended target of DBP <80 mmHg. There are limited data from India regarding physician's choices of anti-hypertensive therapies for a patient with diabetes in single- and multiple-drug based regimens. Therefore, we undertook this study to evaluate treatment patterns in diabetic patients with hypertension, those are being followed at our institute.

Our objectives were.

1. To evaluate the utilization of ACEI or Angiotensin Receptor Blockers (ARBs) and other preferred anti-hypertensive therapies based on the JNC VIII guidelines as agents to treat diabetic hypertension.
2. To compare utilization of different types of antihypertensive therapies in other comorbid conditions
3. To assess BP control in this population.
4. To assess awareness about hypertension in the study group.

METHODS

This study was conducted on diabetic patients who had hypertension as well. Prescribing Pattern of Antihypertensive drugs was analysed on all diabetic patients reporting to Department of Medicine, Ananta Institute of Medical Science and Research Center, Rajsamand, at our institute were screened. Around n=220 patients were recruited on the basis of inclusion and exclusion criteria.

Patients with advance renal failure (serum creatinine >3.5 mg %) and patients with malignant hypertension were excluded. Patients were diagnosed hypertensive if they had at least 2 visits with diagnosis of hypertension or they had prescription of antihypertensive drug with one recording of elevated BP or they had elevated BP on two visits. Elevated BP was defined as systolic BP >139 mmHg and Diastolic BP (DBP) >89 mmHg.[7] Patients were diagnosed as diabetic if they had two visits with diagnosed of diabetes or they had prescription of antidiabetic drugs or insulin or raised glycosylated haemoglobin.

Patients were diagnosed with CAD if they had symptoms suggestive of CAD with ECG evidence or echocardiographic evidence or positive treadmill test or evidence in coronary arteriography. Data of antihypertensive drugs was recorded and grouped according to class of drug. Antihypertensive drugs were grouped in to seven groups - Calcium channel blockers, beta blockers, diuretics, Alfa blockers, Angiotensin Convertase Enzyme Inhibitors (ACEI), Angiotensin Receptor Blockers (ARB), centrally acting drugs. Data for antihypertensive drugs was recorded in form of need of monotherapy, two drugs or three drugs therapy. Data for non-pharmacological therapy was also recorded like salt restriction, loss of weight or exercise.

Table 1: Showing epidemiology data.

Age (years)	Number	Monotherapy	Dual Therapy	Triple Therapy	Quadruple Therapy
<35	26	24	26	6	0
35-50	84	82	52	26	6
50-75	90	80	56	38	8
>75	20	20	12	8	2
Total	220	206	146	78	16

Table 2: Showing utilization of various drugs.

Drug	No. of patients
Angiotensin receptor blocker	100
Calcium channel blocker	86
Diuretic	78
ACE inhibitor	28
Beta blocker	58
Alfa blocker	13
Central agonist	7

Table 3: Description of combination utilization (Dual drug)

Drug Combination	Number	Percentage
ARB+D	22	30.13
CCB+BB	14	20.55
ARB+CCB	14	19.17
ACEI+D	12	16.43
ACEI+BB	10	13.69
Total	72	100

RESULTS

There were 220 patients in this study. Our study group comprised of n=120 males and n = 100 females. Demographic data of patients has been described in Table 1. 46.18% were on monotherapy and remaining patients were on combination antihypertensive drugs. There were total n=486 antihypertensive drug exposures Table 2. Patient needed mean antihypertensive drug of 1.98.

Number of drugs - Monotherapy was needed in 42.58% patients and dual therapy was required in 36.42% patients. 19.75% were on triple drug therapy and 6.25% were on quadruple drug therapy.

Type of drug - Angiotensin receptor blockers were the most commonly prescribed drugs. Angiotensin inhibitors (angiotensin receptor blockers and ACE inhibitors) were utilized in 71% patients. These were followed by calcium channel blockers, diuretics, and beta blockers Table 2.

Combination Utilization pattern - Angiotensin receptor blocker with diuretics was the most commonly used dual drug combination strategy in our study. It was followed by combination of beta blocker with calcium channel blocker, calcium channel blocker with angiotensin receptor blocker, ACE inhibitor with diuretic and ACE inhibitor with beta blocker. Combination utilization pattern has been shown in Table 3. Combination of Beta blocker with calcium channel blocker and diuretic was most commonly (51.28%) used in patients on triple drug combination. Combination of ARB, diuretic with CCB was used in 33.3% and combination of Alfa blocker, BB and diuretic was used in 10.24%. Combination of ACEI, CCB with diuretic was used in 5.12% patients. Combination of ACEI/ARB, diuretic with centrally acting drugs was used in 15.9% patients. Majority patients (50%) on quadruple therapy were on combination of Alfa blocker, diuretic, ACE inhibitor and central agonist. Combination of Alfa blocker, diuretic, central agonist with CCB or ARB was used in remaining 50% patients.

DISCUSSION

Our study tried to find utilization of various antihypertensive drugs in diabetic hypertensive patients and awareness about hypertension. A prescription based study is an effective way to assess and evaluate prescribing attitude of physicians.[10] Majority of patients in our study were on multidrug regimens. Only 42.58% patients were on single drug therapy. It is consistent with other studies.[11,12]

Berlowitz et al.[13] have shown worse BP control in patients with diabetes and less intensive anti-hypertensive medication therapy. ARB was the most common drug prescribed in 44.39% patients either alone or in combination. ACEI/ARB were used in 158 (71%) patients either alone or in combination. Most of the patients (76.6%) on single drug were receiving either ACEI or ARB. There is suggestion that ARBs should be a regular component of combination treatment and preferred drug in patients on monotherapy in diabetics.[14] It has been described that initial monotherapy ACE inhibitors may be superior to dihydropyridine CCB in reducing cardiovascular events.[15,16]

Calcium channel blockers were used in 37.66% patients either in combination or as monotherapy. JNC 8 also recommends calcium channel blockers as first line drug in diabetic hypertensive patient.[7] CCBs ranked second followed by diuretics when considering overall utilization pattern of various anti-hypertensive drugs but Johnson et al found thiazide was second most frequently prescribed drug followed by CCBs and beta blocker. CCBs ranked second followed by diuretics when considering overall utilization pattern of various anti-hypertensive drugs in Indian study.[17] Diuretics were used in 34% patients either as single or combination therapy. Diuretic use ranked third after CCBs and these were more commonly used as part of multidrug regimen. Dhanraj et al. described same pattern in their study on diabetic hypertensives.[18] Beta Blockers were used in 26% patients. Usage of BB was significantly higher in patients with CAD in our study. BB has protective effect in CAD and other studies[19,20] also found higher use of BB in patients with CAD.

ARB/ACEI with diuretic was the most commonly used combination therapy. It is consistent with other study. Patients with nephropathy needed higher no of antihypertensive drugs. Use of ACEI/ARB was higher in patients with nephropathy than without nephropathy. Shah et al.[15] also found similar pattern in their patients. Use of ACEI and ARB has been recommended by ADA9 also. Blood pressure control was achieved in 37.66% patients. Our control rates are better than other studies[19,22] with control rate of 25-32%. Which may be due to difference in sample size. Patients with nephropathy had lesser percentage of patients with control of hypertension than patients without nephropathy. Shah et al[18] also described similar pattern. Awareness about hypertension was found in 81% patients. Asfaq et al. also found awareness in 80% patients attending tertiary care hospital.[22]

CONCLUSION

Our study showed that majority of diabetic hypertensive patients needed multiple drug therapy to control hypertension. Most of the patients were on ARBs/ACE inhibitors. This was according to recommendation by ADA or JNC8. Patients with diabetes had lesser chance of control of hypertension. Hypertension control was achieved in 39% patients. We found awareness rate of 81% in our study group. Still there is room for better control of hypertension and optimization of antihypertensive therapy.

Keywords: cerebral venous thrombosis (CVT), anemia, IDA, neurological deficit

Abstract

Background: Anemia is often considered to be a risk factor for cerebral venous thrombosis (CVT). We investigated the association between anemia and CVT. **Methods**: 42 postpartum /puerperal females were studied retrospectively for various factors like anemia, conscious level at admission, place of delivery (home or hospital) and their neurological sequel was measured at the time of discharge.

Platelets counts were also noted (to rule out thrombocytosis). Anemia was defined according to World Health Organization criteria: non- pregnant women hemoglobin < 7.5 gm/dl, pregnant women < 6.9gm/dl. Modified Rankin Score (mRS) was taken as a scale for recovery. **Results**: *Patients with CVT were younger (mean age 28). Anemia was more frequent in 32.7%. Hemoglobin as a continuous variable was inversely associated with CVT. Platelets counts, BT CT were normal hence no thrombocytosis was seen. No gross increase in WBC count was noted indicating absence of sepsis (puerperal). Outcome was favorable in 83% patients. N=4 (7%) patients died.* **Conclusions**: *We concluded that there is a positive correlation with increased levels of HbA1c and FBS ($p<0.001$) in diabetic postmenopausal women and knee osteoarthritis. we found a significant association of severe anemia and CVT in patients of CVT of non-infectious origin, although the exact mechanism leading to hypercoagulability remains unclear and had poor prognosis.*

Keywords: Echocardiography, Diabetes, Left Ventricular dysfunction

Abstract

Background: *To assess the effect of Hypertension and Diabetes on Left Ventricular Diastolic Function.* **Methods**: *2D Echocardiography was performed in 295 subjects. Subjects were divided into two groups – Group 1 having hypertension (HTN) and Group 2 having diabetes mellitus only (DM). Patients with cardiac illness like heart failure, myocardial infarction, arrhythmias were excluded from the study. The procedure was explained and consent was obtained from the patients. All the subjects underwent detail clinical examination. Height, weight, blood pressure, blood sugar, lipid profile, ECG was done. Early peak Diastolic (E) and late peak diastolic (A) transmitral flow were recorded. E/A was calculated. Data are presented as Mean ± Standard Deviation for continuous variables and as proportions for categorical variables. The X^2 test was used to test differences between proportion. Multiple linear*

regressions were performed to assess the independent association of hypertension and diabetes with Diastolic function parameters. Differences between Hypertension and Diabetes group were assessed by one way analysis of variance. (Performed using STATA). **Results:** *Correlation of hypertension and diabetes with Diastolic function parameters. Diabetes subjects had significantly higher A wave (P<0.05) and lower E/A ratio. No significant differences were observed between hypertension and diabetes groups in any of the Diastolic function parameters.* **Conclusions:** *Prevalence of Diastolic dysfunction of any grade in both subjects were 58.2% (62.2in Hypertension and 54.3% in Diabetes).*

Key words:
Gestational Diabetes, perinatal, glucose challenge, macrosomia

ABSTRACT

Objective: the study was conducted to diagnose the gestational diabetes mellitus (GDM) in early pregnancy using glucose challenge test (GCT) and glucose tolerance test (GTT) and to find out the prevalence of GDM in southern part of Rajasthan and fetomaternal outcome in those GDM patients.

Material and Methods: It was a prospective study carried out in the department of Gynaecology and Obstetrics of a tertiary healthcare centre during the period of 2 years from January 2017 to January 2019. 700 random pregnant women with 18-28 week of gestation were subjected to 50 gram GCT. Women with abnormal GCT were then subjected to 75 gram 2 hour GTT test. Patients were followed up till delivery and perinatal and maternal status were recorded.

Results: The age of the study participants ranges from 18 to 36 years with the mean age of 24±3 years while the mean age of GDM diagnosed women was 28.3±2 years. Out of 700 pregnant women included in the study, 67 women were found to have abnormal GCT and 27 women (3.8%) out of these 67 were found to have abnormal OGTT and were diagnosed with GDM. Most of the GDM patients were having plasma glucose level between 166-175mg/dl (33.33%) followed by 155—165mg/dl (29.62%). There was no fetal loss, no congenital abnormalities; no birth asphyxia in any of the newborns of GDM diagnosed women. 4 out of 27 newborns had macrosomia (weight >4kgs) and 3 newborns had IUGR (weight < 2.5kgs). Mean birth weight was 2.67 kgs.

Conclusion: prevalence of GDM in present study was 3.8%. Routine screening of pregnant women before 28 week of gestation with GCT and GTT should be performed because it is an easy, economical and patient friendly test. Prompt diagnosis and early management can improve maternal and perinatal outcome.

INTRODUCTION

Gestational Diabetes Mellitus (GDM) is defined as any degree of glucose intolerance with the onset of pregnancy or first recognized during pregnancy. [1] Women with history of GDM are at an increased risk of adverse fetomaternal outcome and also at increased risk of future diabetes, predominantly type II including their children. [2] Therefore it is important to diagnose the GDM as early as possible to prevent adverse fetomaternal outcome and complications.

There are many controversies regarding methods of screening and diagnosis of GDM and their cost-effectiveness. Precise level of glucose intolerance which characterizes GDM has also been controversial over past few decades. In 1964, O'Sullivan and Mahan performed study on 752 pregnant women and suggested the use of glucose values in diagnosis of GDM after 3 hour 100 gram oral glucose tolerance test (OGTT).[3]

*Corresponding author: **Dinesh Chandra Sharma**
Department of General Medicine, Ananta Institute of Medical Sciences, Rajsamand

This diagnostic criteria was further modified by National Diabetes Data Group Criteria (NDDG) in 1979 by adjusting diagnostic thresholds upward.[4] This NDDG thresholds were adopted and recommended by American Diabetes Association (ADA) as diagnostic cut-off points for GDM until 1999.[5]

In 2000, ADA revised the recommendation for GDM diagnostic criteria and proposed adoption of Coustan and Carpenter Criteria (CCC) thresholds instead of NDDG thresholds.[6]

The International Association of Diabetes and Pregnancy Study Groups (IADPSG) in 2010 decided to use mean values of fasting, 1 hour and 2 hour blood glucose of all pregnant females as reference and chose to use odds ratio of 1.75 to define the diagnostic cut-offs for GDM, which led to the development of the widely used and accepted IADPSG criteria. [7]

Still there are some controversies regarding screening of pregnant women for GDM. The ADA recommends selective screening for GDM in pregnant women who are at high risk,

while other guidelines, including those of American College of Obstetrics and Gynecologists (ACOG), support screening of all pregnant women for GDM.[8, 9] The present study used the IADPSG criteria (2010) for diagnosing GDM in which fasting OGTT was performed with 75 gram glucose and if fasting plasma glucose (FPG) is ≥126 mg/dl, overt diabetes is diagnosed and if FPG is < 126 mg/dl, then GDM is diagnosed if any one of the values exceeds the threshold shown below:

	Fasting	1 hour	2 hour
Plasma Glucose (mg/dl)	≥92	≥180	≥153

The variation in prevalence of GDM worldwide depends on various screening and diagnostic methods used as well as on age and ethnicity of the pregnant women of the particular region.[10-16] The OGTT is usually performed between the 24th and 28th week of gestation; however, in women with associated risk factors like previous gestational diabetes or family history of diabetes, OGTT should be performed earliest soon after diagnosis of pregnancy.[16] Early screening can avoid serious complications in women with GDM.[17]

The present study is aimed to find out the prevalence and diagnosis of GDM in southern part of Rajasthan with the use of GCT and OGTT and fetomaternal outcome in the patients of GDM.

MATERIAL AND METHODS

The present study was a prospective study carried out in the department of Gynaecology and Obstetrics, Ananta institute of medical sciences, Rajsamand during the period of 2 years from January 2017 to January 2019.

700 pregnant women with gestation of 18-28 week were randomly recruited from the antenatal clinic of our institute. All the 700 women were given 50 gram glucose load for glucose challenge test (GCT) without regard to the time of last meal and the venous blood samples were collected after 1 hour for estimating plasma glucose. GCT was marked abnormal if 1 hour plasma glucose was > 140 mg/dl (7.77 mmol/L).

All the women with abnormal results were then subjected to 2 hour 75 gram oral glucose tolerance test (OGTT) for confirmation. In OGTT, initial blood sample was taken after overnight fasting and the patient was then asked to drink solution of 75 gram glucose in 200 ml water. If fasting plasma glucose (FPG) was ≥126 mg/dl, overt diabetes was diagnosed and if FPG was < 126 mg/dl, then GDM was diagnosed if any one of the values exceeds the threshold as shown below:

	Fasting	1 hour	2 hour
Plasma Glucose (mg/dl)	≥92	≥180	≥153

Patients were followed up till delivery and maternal and perinatal status was recorded.

RESULTS

The age of the study participants ranges from 18 to 36 years with the mean age of 24±3 years.

Out of 700 pregnant women included in the study, 67 women were found to have abnormal GCT and these 67 women were then subjected to 2 hour, 75 gram OGTT. 27 women (3.8%) out of 67 were found to have abnormal OGTT and were diagnosed with GDM. The mean age of the GDM diagnosed women was 28.3±2 years.

Most of the GDM patients were having 2 hour plasma glucose level between 166-175mg/dl (33.33%) followed by 155—165mg/dl (29.62%). (Table 1)

Table 1 Range of plasma sugar level in GDM patients

Plasma sugar level (mg/dl)	Number of patients	Percentage
155-165	8	29.62
166-175	9	33.33
176-185	7	25.92
>185	3	11.11
Total	27	100%

There was no fetal loss, no congenital abnormalities; no birth asphyxia in any of the newborns of GDM diagnosed women. 4 out of 27 newborns had macrosomia (weight >4kgs) and 3 newborns had IUGR (weight < 2.5kgs). Mean birth weight was 2.67 kgs.

DISCUSSION

The worldwide prevalence of gestational diabetes ranges from 1-14%. [18, 19]

In India, prevalence rates reported to be between 4.6% and 14% in urban areas, and 1.7% and 13.2% in rural areas. [20] In present study, the overall prevalence of GDM was 3.8%. The figure was comparable to the studies done in the past by Indian workers like Maheshwari *et al* and Kumar *et al* with the prevalence of GDM 4.9% and 5.5% respectively. [21, 22]

The mean age of all study participants in present study was 24±3 years while the mean age of GDM diagnosed women was 28.3±2 years. Similar results were obtained in the study by Ismail NA *et al* who reported the mean age of 27.9 years in GDM patients. [23] Hence increasing age of patient was significantly associated with GDM.

High perinatal mortality rate in uncontrolled GDM patients has been reported by O'Sullivan JB *et al* in 1973. [24] Similarly, Fareed P *et al* showed 9% perinatal mortality in GDM patients compared to 1% in control group. [25] The results were in contrary to the results of present study. In present study, there was no perinatal mortality and no congenital malformation was there. Mean birth weight of the newborns was 2.67 kgs. This could be made possible because of early screening for GDM and management of the patients.

4 out of 27 newborns (14.81%) had macrosomia (weight >4kgs) and 3 newborns (11.11%) had IUGR (weight < 2.5kgs). This observation was comparable to past studies done by Fareed P *et al*, Wahi P *et al* and Bener AB *et al* where macrosomia was found 17%, 16.2% and 10.3% respectively. [25, 26, 27]

CONCLUSION

The study concluded that the prevalence of GDM is 3.8% in southern area of Rajasthan. Increasing age of pregnancy is significantly associated with GDM. We advocate the routine screening of pregnant women before 28 week of gestation with 50 gram GCT, because it is an easy, economical and patient friendly test as patient need not to come fasting for this test. Patients who have abnormal value in GCT should be subjected to GTT for confirmation of GDM. Prompt diagnosis and early management can improve maternal and perinatal outcome.

Abstract

Background: *Diabetes mellitus is now affecting individuals of all age group and socioeconomic status. Besides other complications of the diabetes mellitus, skin is affected by the acute metabolic derangements as well as by chronic degenerative complications of diabetes. To evaluate the prevalence of skin manifestations in patients with diabetes mellitus. To analyze the prevalence and pattern of skin disorders among diabetic patients in North part of Uttar Pradesh.*

Methods: *This Prospective study was conducted on 40 diagnosed Type 2 diabetic patients having skin lesions attending the Department of Medicine, Ananta Institute of Medical Sciences & Research Center, Rajsamand, Rajasthan were included in our study on the basis of inclusion and exclusion criteria. Out*

of 40 patients, only 25 patients were completed the whole study done during the duration of 3 months (March 2016 to May 2016.

Results: *The common skin disorders were: diabetic dermopathy (44%), Xerosis (36%), skin tags (32%), cutaneous infections (31%), and seborrheic keratosis (30%).*

Conclusions: *Skin is involved in diabetes quite often and the manifestations are numerous. Most of the patients were affected from Diabetic dermopathy.*

Abstract

Introduction: *Diabetes Mellitus has been closely associated with Hypertension. Hypertension is major risk factor for development of diabetes as well for complications like nephropathy, CAD and neuropathy etc. Therefore, controlling Hypertension is vital to prevent and retard progression of microvascular and macrovascular complications. Therefore, we undertook this study to evaluate treatment patterns in diabetic patients with hypertension, those are being followed at our institute.*

Materials and Methods: *This study was conducted on diabetic patients who had hypertension as well attending Medicine department of Ananta Institute of Medical Sciences & Research Center, Rajsamand, Rajasthan. Antihypertensive drugs were analysed on all diabetic patients reporting to medicine OPD from February 2016 to April 2016 at our institute were screened.*

Results: *Around 145 patients were included in our study. Out of 145 patients, only n=112 patients completed our study. Out of n=112 patients, 62 were males and 50 were females. Mean age of group was 52.5 years. N=33 patients were on monotherapy and remaining patients were on combination antihypertensive drugs. There were total 331 antihypertensive drug exposures. Angiotensin receptor blockers were the most commonly prescribed drugs. Angiotensin inhibitors (angiotensin receptor blockers and ACE inhibitors) were utilized in n=150 patients.*

Conclusion: *Our study showed that majority of diabetic hypertensive patients needed multiple drug therapy to control hypertension. Most of the patients were on ARBs/ACE inhibitors. This was according to recommendation by ADA or JNC8.*

ABSTRACT

Objective: The present study was carried out to find out the prevalence of various thyroid disorders among pregnant women in their first trimester in the southern area of Rajasthan.
Material & Methods: The study was conducted during the period of 1year from July 2017 to July 2018. 200 pregnant women attending antenatal clinic for their routine antenatal visit in first trimester were included in the study. Routine blood and urine investigations along with serum TSH, FT3 and FT4 were done in all the study participants.
Results: Age of the patient's ranged from 19 to 38 with the mean age of 25.66±3.90 years. Mean gestational age of study population was 8.12±1.63 weeks. The mean TSH, FT3 and FT4 values were 1.499, 2.386 and 1.410 respectively. Thyroid disorders were found in 14%patients out of 200 study participants. 86% patients were euthyroid among the study participants. 7% patients were found to be having subclinical hypothyroidism. 4% were having overt hypothyroidism and 3% were having subclinical hyperthyroidism.
Conclusion: The study revealed high prevalence of thyroid disorders (14%) among pregnant women in their first trimester specially hypothyroidism (11%). Routine antenatal thyroid screening should be performed in all pregnant women.

Keywords: Hypothyroidism, antenatal, hyperthyroidism, eclampsia

INTRODUCTION

Normal thyroid hormone levels are necessary in maintaining pregnancy and in development of fetus. Thyroid dysfunctions are more common in female than in male. Maternal thyroid functions changes during pregnancy and leads to thyroid disorders in absence of adaptation to these changes. Thyroid disorders during pregnancy can result in substantial adverse fetomaternal outcomes. Furthermore, thyroid dysfunction can be readily diagnosed with simple and reliable blood tests and easily corrected with economical and easily available treatments. [1]

Worldwide, thyroid disorders are common in women of child-bearing age. [2] During pregnancy, demands on the hypothalamic-pituitary-thyroid axis increases which commonly leads to borderline thyroid abnormalities. Both hyper and hypo-thyroidism types of thyroid disorders can occur during pregnancy and correction of these disorders dramatically reduces the risk of adverse fetomaternal outcomes like foetal loss, preterm birth, pre-eclampsia and eclampsia and maternal morbidity. [3,4]

According to the western literature, the prevalence of hypothyroidism in pregnancy is around 2.5%. The prevalence of gestational diabetes is around 0.1–0.4% and that of thyroid autoimmunity (TAI) is around 5-10%. [5]

There are very few data from India about the prevalence of thyroid dysfunction in pregnancy especially in the southern Rajasthan. With this background, the present study aims to find the prevalence of thyroid disorders including hyperthyroidism, hypothyroidism and Subclinical Hypo and hyper- thyroidism during pregnancy in southern part of Rajasthan.

MATERIALS AND METHODS

The present study was a prospective study carried out in the department of Gynaecology and Obstetrics, Ananta institute of medical sciences, Rajsamand during the period of 1 year from July 2017 to July 2018.

200 patients attending OPD in their first trimester for routine antenatal check up were randomly selected and included in the study.

Inclusion criteria:

1. ≤ 12 week gestation
2. Singleton pregnancy
3. Primi/ multigravidae

Exclusion criteria:

1. Patients who were not willing to give consent.

Procedure:

Detailed history of all the patients was taken regarding symptoms of thyroid disorders, past medical and obstetric history, family history and personal history. Complete general and systemic examination was done in all the patients. Per abdominal and per vaginal examination were also done and findings were recorded.

Routine blood and urine investigations along with serum TSH, FT3 and FT4 were done in all the study participants. Pregnancy ≤12 week was confirmed by clinical examination, pregnancy test and ultrasonography. The reference ranges of the test values used in this study were as per the Guidelines of American Thyroid Association (ATA) for the diagnosis and management of thyroid disease during pregnancy and postpartum. As per regulation 14.2 of ATA Guidelines, if trimester specific ranges for TSH are not available in the laboratory, the following normal reference ranges are recommended: 1st trimester - 0.1 to 2.5 m IU/L, 2nd trimester - 0.2 to 3.0 m IU/L and 3rd trimester - 0.3 to 3.0 m IU/L. Normal free T4 level is 0.7 to1.8 ng/ml and free T3 level is 1.7 to 4.2 pg/ml.

Ethical consideration: Permission was taken from institutional ethical committee and written consent was taken from all the study participants.

RESULTS

200 pregnant women in their first trimester were included in present study. Age of the patients ranged from 19 to 38 with the mean age of 25.66±3.90 years. Mean gestational age of study population was 8.12±1.63 weeks.

The mean TSH, FT3 and FT4 values were 1.499, 2.386 and 1.410 respectively. (Table 1)

Table.1 Baseline parameters of the study participants

S.No.	Parameters	Value (Mean ±SD)
1	Age	25.66±3.90 years
2	Gestational Age	8.12±1.63 weeks
3	TSH	1.499±0.324 IU/L
4	FT3	2.386±0.537 ng/ml
5	FT4	1.410±0.461 pg/ml

Thyroid disorders were found in 28 cases (14%) out of 200 study participants. Table 2 illustrates variety of thyroid disorders in the study population. 86% patients were euthyroid among the study participants. 7% patients were found to be having subclinical hypothyroidism. 4% were having overt hypothyroidism and 3% were having subclinical hyperthyroidism.

Table 2. Percentage of thyroid disorders in study participants

S.No.	Type	Number	Percentage
1	Euthyroid	172	86
2	Overt Hypothyroidism	8	4
3	Subclinical hyperthyroidism	6	3
4	Subclinical hypothyroidism	14	7
5	Overt Hyperthyroidism	0	0
6	Total	200	100

DISCUSSION

The present prospective study was conducted in a tertiary healthcare centre of southern Rajasthan. 200 pregnant women

with ≤12 weeks of gestation, who met the inclusion criteria, were included in the study.

The prevalence of thyroid disorders was 14% in present study. Many studies done in the past had similar results. Taghavi et al found 14.6% prevalence of thyroid disorders in their study. [6] Ajmani et al found 13.25% cases of thyroid disorders in their study. [7] Similarly, Weiwei Wang et al (10.2%), Sahu et al (12.7%) and Dhanwal DK et al (14.3%) had comparable results in their studies. [8-10]

The prevalence of thyroid disorder was very less (5%) in a study conducted by Thanuja PM et al [11], while the prevalence was very high (26.5%) in a study by Rajput et al [12], hence the results of these studies were in contrary with present study.

The prevalence of subclinical hypothyroidism in present study was 7%. In a study done by Sangeeta Pahwa et al, the prevalence of subclinical hypothyroidism was 6%. [13] Similarly, in a study by Sahu MT et al, the prevalence was 6.47% which is also comparable to our study. [9]

All women who have been diagnosed subclinical hypothyroidism during pregnancy should be tested for antithyroid antibodies because it can be associated with other autoimmune disorders like type I diabetes and can have adverse fetomaternal outcome. [14,15] ATA updated its guidelines in 2017 for the management of thyroid disorders in pregnancy. They suggested that Thyroxine should be started if antithyroid antibodies are present and initial level of TSH is 2.5- 4 mIU/L. If initial TSH level is > 4mIU/L, then Thyroxine should be started irrespective of the status of antithyroid antibodies. Usually the Thyroxine is started in the dose of 50 microgram per day to treat subclinical hypothyroidism and thyroid function tests are repeated after 4 weeks of starting treatment. [16, 17]

The prevalence of overt hypothyroidism in present study was 2%, which was consistent with the results obtained by Saraladevi et al with the prevalence of 2.8% [18] and partly consistent with the results obtained by Sahu MT et al, in which the prevalence was 4.58%. [9]

In present study, prevalence of subclinical hyperthyroidism and overt hyperthyroidism were 3% and 0% respectively. The prevalence of subclinical and overt hyperthyroidism was 0.5 and 0.4% respectively in the study done by Stagnaro Green A. [17] Similarly in the study done by Saraladevi et al the prevalance were 1.8% and 0.6% respectively. [18]

Our study had few limitations that fetomaternal outcomes were not included in the study. The sample size was also small. Hence, further researches with large sample size are advisable.

CONCLUSION

The study revealed high prevalence of thyroid disorders (14%) among pregnant women in their first trimester specially hypothyroidism (11%). Hyperthyroid disorders are rare in pregnant women. Due to immense impact of thyroid disorders on the fetomaternal outcome, we advocate the routine antenatal thyroid screening.

ABSTRACT

Background: World health organization also reported that as the high prevalence of dengue infection seen worldwide it requires immediate action and planning to combat the situation. It is reported that globally more than 2.5 billion of population living in the areas which are endemic for dengue viral infection. Approximately near about 50 million new dengue infections reported each year. **Material & Methods:** The present cross-sectional study includes 100 Patients who had dengue IgM antibody positive were enrolled from outdoor and from ward by simple random sampling. Clearance from Institutional Ethics Committee was taken before start of study. Written informed consent was taken from each study participant. **Results:** 92 % patients had myalgia which was followed by headache in 86% patients, 84% patients had retro-orbital pain and 83% patients had vomiting. Out of the total pain abdomen was present among 72% patients, bleeding tendencies were found among 21% patients, petechiae/purpura was present in 13% patients. Oliguria was found among 2% patients, 1% patient had altered sensorium and convulsions was present among 1% patient. **Conclusion:** The common presenting symptoms of dengue viral infections were fever, headache, myalgia, retro orbital pain, vomiting, pain abdomen, purpura and bleeding tendencies. The most common presenting sign was skin rash followed by ascites and splenomegaly. The most common presented complication was hepatic dysfunction.

Key words: Dengue fever, Clinical profile, Complications.

INTRODUCTION

The prevalence of dengue viral infection has tended to rise globally in the recent decades (1). According to the World Health Organization about forty percent of the world's population reported that in current scenario is at risk for encountering dengue viral infection (2). Dengue is an emerging epidemic disease and several outbreaks among every state of India is being reported from time to time (3). In India the burden and prevalence of dengue viral infection is increasing as trends reported globally. Hence, along with global pandemic concern dengue has become major public health concern in India.

The etiology behind dengue is reported as vector borne viral diseases which is transferred to humans by the bite of the infected Aedes mosquito. It was also reported that the number of dengue vector (Aedes mosquito) also increased which is also contributing in the high prevalence of dengue viral infections (4).

Due to its high incidence and prevalence rates of dengue viral infections in India, national vector borne diseases control program is initiated for integrated management of vector, surveillance and monitoring and diseases prevention along with

patients which was followed by ascites among 28% patients. Hepatomegaly was found among 24% patients and splenomegaly was found among 9% patients. Positive tourniquet test was reported among 13% patients. (Table 2)

Table 2: distribution of study subjects based on signs

Signs	Number of Patients
Skin rash	56%
Ascites	28%
Hepatomegaly	24%
Tourniquet test (positive)	13%
Splenomegaly	9%

In the present study, out of total 100 study participants, on the assessment of complications of dengue fever it was found that, hepatic dysfunction was the most common presented complication which was present among 36% patients which was followed by shock reported among 3% of patients. pleural effusion was reported among 2% patients and acute renal failure was reported among 2% cases. Severe hemorrhage and encephalitis were present among 1% patients respectively. (Table 3)

Table 3: distribution of study subjects based on complications of dengue fever.

Complications	Number of patients
Hepatic dysfunction	36%
Shock	3%
Pleural effusion	2%
Renal failure	2%
Severe hemorrhage	1%
Encephalitis	1%

DISCUSSION

Dengue is an emerging epidemic disease and several outbreaks among every state of India is being reported from time to time (3). In Inia the burden and prevalence of dengue viral infection is increasing as trends reported globally. Hence, along with global pandemic concern dengue has become major public health concern in India. The etiology behind dengue is reported as vector borne viral diseases which is transferred to humans by the bite of the infected Aedes mosquito. It was also reported that the number of dengue vector (Aedes mosquito) also increased which is also contributing in the high prevalence of dengue viral infections (4). In the present study we enrolled 50 patients who were aged from 18 to 71 years. The mean age of the enrolled patient was 42.36 ± 5.19 years. There was no patient in the present study who aged less than 15 years of age. Out of total patients diagnosed dengue IgM antibody positive 58% were male and 42% were females. All of these patients with dengue viral fever were subjected for routine blood investigation for complete blood count and liver function test and ELISA for dengue serology. Similar results were obtained in a study conducted by Aggarwal A et al among patients of dengue viral fever and found similar results with present study (9).

Out of the total study participants, all of them were presented with fever. 92 % patients had myalgia which was followed by headache in 86% patients. 84% patients had retro-orbital pain and 83% patients had vomiting. Out of the total pain abdomen was present among 72% patients. bleeding tendencies were found among 21% patients, petechiae/purpura was present in 13% patients. Oliguria was found among 2% patients. 1% patient had altered sensorium and convulsions was present among 1% patient. Similar results were obtained in a study conducted by Chandralekha et al among patients of dengue viral fever and found similar clinical profile patterns among study participants (10). Similar results were obtained in a study conducted by Selvan T et al among patients of dengue viral fever and found fever was the most common symptom which was followed by myalgia and retroorbital pain, vomiting and convulsions and altered sensorium (11).

In the present study, out of total 100 study participants, on the assessment of signs of dengue fever it was found that, skin rash was the most common presenting sign reported among 56% patients which was followed by ascites among 28% patients. Hepatomegaly was found among 24% patients and splenomegaly was found among 9% patients. Positive tourniquet test was reported among

ABSTRACT

Background: The prevalence of non-communicable diseases is increasing compared to communicable diseases. Among the non-communicable diseases, diabetes mellitus is rapidly increasing globally and affecting all the age groups. Diabetes is a chronic disease in etiology and occurs when the pancreas does not produce enough amount of insulin or when there is resistance towards its action on the body. **Material & Methods:** In the present study a total 200 patients with type 2 diabetes mellitus and confirmed with laboratory investigations were enrolled from outdoor and from ward by simple random sampling. Clearance from Institutional Ethics Committee was taken before start of study. Written informed consent was taken from each study participant. **Results:** The mean value of total cholesterol among study participants was 194.2 ± 36.4 mg/dl, mean value of HDL- cholesterol was 32.4 ± 6.2 mg/dl, mean value of LDL- cholesterol was 112.8± 42.5 mg/dl and mean value of Serum triglycerides was 201.6 ± 58.7 mg/dl. 32 (16%) diabetes patients had diabetic Nephropathy. On the estimation of GFR, it was found that Out of total diabetic patients, 168 (84%) diabetic patients had GFR > 90 ml/min/1.73 m2, 30 (15%) diabetic patients had GFR of 60-90 ml/min/1.73m2 and 02 (1%) diabetic patients had GFR < 60 ml/min/1.73 m2. There was a significant association found between High LDL-cholesterol, High serum triglycerides and High total cholesterol levels. (p value < 0.05). **Conclusion:** We concluded from the present study that there was a significant association was found between dyslipidemia and diabetic nephropathy in patients with type 2 diabetes mellitus. Hence, serum lipid profile should be investigated annually among all the patients of diabetes.

Key words: Diabetes mellitus, Diabetic nephropathy, Dyslipidemia.

INTRODUCTION

The prevalence of non-communicable diseases is increasing compared to communicable diseases. Among the non-communicable diseases, diabetes mellitus is rapidly increasing globally and affecting all the age groups. Diabetes is a chronic disease in etiology and occurs when the pancreas does not produce enough amount of insulin or when there is resistance towards its action on the body. In 2014, WHO reports that 8.5% of adults who aged 18 years or above had diagnosed with diabetes. In 2016, WHO reports that diabetes was the directly responsible for 1.6 million mortality occurred worldwide. It was estimated that by the year 2030 diabetes will became seventh leading cause of mortality worldwide (1).

In India, the prevalence of diabetes is increasing and imposing challenges on health care infrastructure of the country. The overall prevalence of diabetes reported by WHO was 8.7% among the age group of 20 and 70 years. This rising prevalence depends on

various factors such as, sedentary lifestyles, rapid urbanization, unhealthy diets and substance use/abuse along with increasing life expectancy. Obesity and overweight are also the most important associated risk factors. The onset of diabetes can be prevented or delayed by life style and behavioral changes by taking healthy diet and routine physical activity (2).

The diabetes has several microvascular and macrovascular complications which are responsible for several serious complications. Dyslipidemia in diabetes characterized by abnormalities in patient's lipid profile associated with changes in quantity and quality of serum lipoproteins. These changes in serum lipoproteins leads to vascular complications such as coronary heart disease, atherosclerosis and several other macrovascular complications. Diabetes mellitus is most common leading cause of end stage renal disease. Diabetic nephropathy is accounts for mortality and morbidity among more than 20% of patients with diabetes mellitus (3). Hence, the association of dyslipidemia in macro vascular complications has been well studied. Therefore, we conducted the present study to elaborate and find the role of serum lipid profile among the cases of diabetic nephropathy.

MATERIALS & METHODS

The present prospective study was conducted at department of general medicine of Pacific Medical College & Hospital, Udaipur. The study duration was of one year from Oct. 2016 to Nov. 2017. A sample size of 200 was calculated at 95% confidence interval at 10% acceptable margin of error by epi info software version 7.2. Patients who were presenting with type 2 diabetes mellitus and confirmed with laboratory investigations were enrolled from outdoor and from ward by simple random sampling. Clearance from Institutional Ethics Committee was taken before start of study. Written informed consent was taken from each study participant.

The data were collected by detailed history, general physical and clinical examination from each patient after taking the written consent. The hematological investigation was done for fasting and post prandial blood sugar, glycosylated hemoglobin (HbA1c), fasting lipid profile, 24 hour urine protein, serum creatinine levels, spot urine albumin levels and spot urine albumin creatinine ratio. Dyslipidemia was considered if the values of, TG≥150 mg/dl, S. LDL≥ 100mg/dl, S. HDL value ≤40 mg/dl (male) and ≤50 mg/dl (female) and TC more than 200 mg/dl (4). GFR estimation was done by using Crockroft-Gault equation. Patients who had hypertension, patients taking drugs for lipid lowering or drugs which can alter lipid profile and BMI> 30 kg/m2 were excluded from the present study. Data analysis was carried out using SPSS v22. All tests were done at alpha (level significance) of 5%; means a significant association present if p value was less than 0.05.

RESULTS

In the present study we enrolled 200 patients of diabetes mellitus who were aged from 28 to 60 years. The mean age of the enrolled patients was 38.91 ± 7.56 years. Out of total patients diagnosed with diabetes mellitus 116 (58%) patients were male and 84 (42%) patients were females. On the detailed history and laboratory investigation it was found that mean duration of diabetes mellitus was 5.64 ± 4.23 years. Mean level of HbA1C was 8.45 ± 1.69. We found the mean fasting blood sugar was 167.6 ± 21.2 mg/dl and mean post prandial blood sugar was 265.7 ± 32.6 mg/dl. The dyslipidemia was found among 114 (57%) patients in our study and it was found that 32 out of 116 males and 25 out of 84 females were diagnosed with dyslipidemia, i.e. the prevalence of dyslipidemia among males was 27.6% whereas among females was 29.8%. (Table 1)

Table No.-1: Distribution of patients according to study parameters.

Study parameters	No. of Patients (%)
Male	116 (58%)
Female	84 (42%)
Mean age	38.91 ± 7.56 years
Mean duration of diabetes mellitus	5.64 ± 4.23 years
Mean HbA1C	8.45 ± 1.69
Mean fasting blood sugar	167.6 ± 21.2 mg/dl
Mean post prandial blood sugar	265.7 ± 32.6 mg/dl
Prevalence of dyslipidemia	114 (57%)

In the present study, combined serum lipid profile abnormalities were found among majority of

cholesterolemia patients. Among the patients with combined dyslipidemia, we found raised serum triglycerides and low HDL- cholesterol levels in higher frequencies among both males and females. This abnormality in serum lipid profile is followed by isolated dyslipidemia associated with decreased levels of HDL- cholesterol among both males and females. The mean value of total cholesterol among study participants was 194.2 ± 36.4 mg/dl, mean value of HDL- cholesterol was 32.4 ± 6.2 mg/dl, mean value of LDL- cholesterol was 112.8± 42.5 mg/dl and mean value of Serum triglycerides was 201.6 ± 58.7 mg/dl. We found a statistically significant association control (p value < 0.05) with dyslipidemia and HbA1C more than 7(poorly controlled diabetes mellitus). (Table 2)

Table No.-2: Mean values of serum lipid profile in our study.

Lipid parameter	Mean +SD
Total cholesterol	194.2 ± 36.4 mg/dl
HDL- cholesterol	32.4 ± 6.2 mg/dl
LDL- cholesterol	112.8± 42.5 mg/dl
Serum triglycerides	201.6 ± 58.7 mg/dl

In present study, out of total two hundred enrolled study participants, 32 (16%) diabetes patients had Diabetic Nephropathy. Out of these 32 (16%) diabetic nephropathy patients 28 (14%) presented with micro albuminuria and 04 (2%) presented with macro albuminuria. On the estimation of GFR, it was found that Out of total diabetic patients, 168 (84%) diabetic patients had GFR > 90 ml/min/1.73 m2. 30 (15%) diabetic patients had GFR of 60-90 ml/min/1.73m2 and 02 (1%) diabetic patients had GFR < 60 ml/min/1.73 m2. There was a significant association found between High LDL-cholesterol, High serum triglycerides and High total cholesterol levels (p value < 0.05) (Table 3)

Table No.-3: Distribution of patients according to study parameters.

Study parameters	No. of Patients (%)
Diabetic Nephropathy	32 (16%)
micro albuminuria	28 (14%)
macro albuminuria	04 (2%)
GFR > 90 ml/min/1.73 m2	168 (84%)
GFR - 60-90 ml/min/1.73m2	30 (15%)
GFR < 60 ml/min/1.73 m2	02 (1%)

DISCUSSION

In the present study we enrolled 200 patients of diabetes mellitus who were aged from 28 to 60 years. The mean age of the enrolled patients was 38.91 ± 7.56 years. Out of total patients diagnosed with diabetes mellitus 116 (58%) patients were male and 84 (42%) patients were females. On the detailed history and laboratory investigation it was found that mean duration of diabetes mellitus was 5.64 ± 4.23 years. Mean level of HbA1C was 8.15 ± 1.69. We found the mean fasting blood sugar was 167.6 ± 21.2 mg/dl and mean post prandial blood sugar was 265.7 ± 32.5 mg/dl. The dyslipidemia was found among 114 (57%) patients in our study and it was found that 22 out of 116 males and 25 out of 84 females were diagnosed with dyslipidemia. I.e. the prevalence of dyslipidemia among males was 19.6% whereas among females it was 29.8%. Similar results to the present study was found in a study conducted by yadav SK et al among patients of type 2 diabetes mellitus to found the association between serum dyslipidemia and diabetic nephropathy and they found the overall prevalence of serum dyslipidemia was 70% (5). Similar results to the present study was found in a study conducted by Hetal Pandya et al et al among patients of type 2 diabetes mellitus to found the association between serum dyslipidemia and diabetic nephropathy and they found the overall prevalence of serum dyslipidemia was 72% (6).

In the present study, combined serum lipid profile abnormalities were found among majority of dyslipidemia patients. Among the patients with combined dyslipidemia, we found raised serum triglycerides and low HDL- cholesterol levels in higher frequencies among both males and females. This abnormality in serum lipid profile is followed by

Published by Association for Scientific and Medical Education (ASME)

isolated dyslipidemia associated with decreased levels of HDL- cholesterol among both males and females. The mean value of total cholesterol among study participants was 194.2 ± 36.4 mg/dl, mean value of HDL- cholesterol was 32.4 ± 6.2 mg/dl, mean value of LDL- cholesterol was 112.8± 42.5 mg/dl and

mean value of Serum triglycerides was 201.6 ± 58.7 mg/dl. We found a statistically significant association control (p value < 0.05) with dyslipidemia and HbA1C more than 7 (poorly controlled diabetes mellitus). Similar results to the present study was found in a study conducted by Daniel Nii Aryee Tagoe et al et al among patients of type 2 diabetes mellitus to found that the overall prevalence of serum dyslipidemia was 93%. They found raised serum triglycerides and low HDL- cholesterol levels in higher frequencies among both males and females (7). Similar results to the present study was found in a study conducted by Jayarama N et al et al among patients of type 2 diabetes mellitus to found that combined serum lipid profile abnormalities among majority of patients (8).

In present study, out of total two hundred enrolled study participants, 32 (16%) diabetes patients had diabetic Nephropathy. Out of these 32 (16%) diabetic nephropathy patients 28 (14%) presented with micro albuminuria and 04 (2%) presented with macro albuminuria. On the estimation of GFR, it was found that Out of total diabetic patients, 168 (84%) diabetic patients had GFR > 90 ml/min/1.73 m2, 30 (15%) diabetic patients had GFR of 60-90 ml/min/1.73m2 and 02 (1%) diabetic patients had GFR < 60 ml/min/1.73 m2. There was a significant association found between High LDL-cholesterol, High serum triglycerides and High total cholesterol levels. (p value < 0.05). Similar results to the present study was found in a study conducted by Vinod M R et al et al among patients of type 2 diabetes mellitus (9). Similar results to the present study was also found in a study conducted by Prashant Tayde et al et al among patients of type 2 diabetes mellitus (10). Similar results to the present study was also found in a study conducted by Kanakamani J et al et al among patients of type 2 diabetes mellitus and found that microalbuminuria among 24 % diabetic patients and macroproteinuria among 6% diabetic patients (11). Similar results to the present study was also found in a study conducted by Macisaac RJ and Jerums G among patients of type 2 diabetes mellitus and found that 20 % patients have GFR <60ml/min/1.73m2 (12). Similar results to the present study was also found in a study conducted by Toth PP among patients of type 2 diabetes mellitus and found that dyslipidemia is significantly associated with diabetic nephropathy (13).

CONCLUSION

We concluded from the present study that there was a significant association was found between dyslipidemia and diabetic nephropathy in patients with type 2 diabetes mellitus. Hence, serum lipid profile should be assessed annually among all the patients of diabetes. Screening for Diabetic Nephropathy done by estimation of urinary albumin and creatinine.

Abstract

Background: Alcohol consumption affects both mental and physical function of the body and hence called as "dual disease" because it has mentioned in etiology of morbidity in both the components of the body. According to the reports of World Health Organization there were more than 150 million people worldwide has indulged with alcoholism.

Material & Methods: The present prospective study was conducted at department of general medicine of our tertiary care hospital. 100 Patients who were diagnosed as acute onset alcoholic liver disease were enrolled from outdoor and from ward by simple random sampling.

Results: The most common clinical feature recorded among study participants was of nausea and vomiting seen in 46 (92%) of patients, which was followed by jaundice reported among 43 (86%) of patients. Hepatomegaly was reported among 37 (74%) of patients, which was followed by signs of liver failure reported among 30 (60%) patients, followed by anorexia reported among 29 (58%) of patients. Splenomegaly was reported among 17 (34%) of patients, fever was reported among 13 (26%) of patients, abdominal pain was reported among 12 (24%) of cases and ascites was reported among 8 (16%) study participants.

Conclusion: We concluded from the present study that larger quantities of alcohol consumption for a longer duration of time result in high morbidity and mortalities. Alcoholic liver disease is not only a medical burden but also a social burden which leads to frequent hospitalization and unwanted out of pocket expenditure.

Key words: alcoholic liver disease, liver cirrhosis, hepatomegaly.

Introduction:

Alcohol consumption affects both mental and physical function of the body and hence called as "dual disease" because it has mentioned in etiology of morbidity in both the components of the body. According to the reports of World Health Organization there were more than 150 million people worldwide has indulge with alcoholism (1). Several studies had reported that alcoholism affect the biological mechanisms which involves in equilibrium of multiple organs of human body along with this it directly have adverse effect on social environment of the person involving family life, mental health and also the vocational capabilities (2). Alcohol act as central nervous system depressant in higher blood concentration, however in low doses it act as central nervous system behavioral stimulant (3). Alcoholism is reported to be significantly associated with high mortality and morbidity rates, which accounts for more than 4% of the mortality reported worldwide and also for near about 5% of the DALYs lost worldwide (4).

Alcoholic liver disease has reported to have group of diseases disease ranging from mild liver steatosis to severe liver cirrhosis. The most common etiology behind this ranging disease spectrum reported was chronic and excessive alcohol consumption (5). In India also alcoholism is reported for the most prevalent cause of acute and chronic liver diseases (6). Alcoholic liver disease ranges from mild fatty liver, alcoholic hepatitis and alcoholic cirrhosis. Among them alcoholic hepatitis and severe liver cirrhosis are life threatening conditions and sometimes fatal (7). However, many other factors are also associated in the outcome of the alcoholic liver diseases like, amount and duration of alcohol content, nutritional deficiency, iron overload, viral hepatitis and several genetic factors (8). Hence, we conducted present study to assess the clinical profile of alcoholic live disease.

MATERIALS & METHODS

The present prospective study was conducted at department of general medicine of our tertiary care hospital. The study duration was of six months from July 2018 to December 2018. A sample size of 50 was calculated at 95% confidence interval at 10% acceptable margin of error by epi info software version 7.2. Patients who were diagnosed as acute onset alcoholic liver disease were enrolled from outdoor and from ward by simple random sampling. Clearance from Institutional Ethics Committee was taken before start of study. Written informed consent was taken from each study participant.

The data were collected by detailed history, general physical and clinical examination from each patient after taking the written consent. The hematological investigation was done for routine blood investigation and liver function test. Patients who had chronic diseases such as cardiac diseases, renal diseases, hypertension and cancer were excluded from the study. Data analysis was carried out using SPSS v22. All tests were done at alpha (level significance) of 5%; means a significant association present if p value was less than 0.05.

RESULTS

In the present study we enrolled 50 patients who were aged from 21 to 59 years. The mean age of the enrolled patient with alcoholic liver disease was 36.42 ± 4.78 years. There was no patient in the present study who aged less than 18 years of age. Out of total patients diagnosed with alcoholic liver disease 94% were male and 6% were females. In the present study, majority of the patients were in the age group of 31-40 years (52%) which is followed by 24% of the patients were in the age group of 21- 30 years followed by 14% of the patients were in the age group of 41-50 years and 10% of patients were in the age group of 51-60 years. In our study majority of patients were farmers which is followed by employed at private service and daily wages workers. In the present study, according to the of alcohol consumption majority of the patients were consumed alcohol intake more than 60 gm which is followed by patients who were consuming alcohol 50 - 60 gm in 24 hours and lastly patients who had history of alcohol consumption of less than 50 gm in 24 hours. On the basis of consumption, majority of the patients had alcohol consumption of more than five years which is followed by alcohol consumption for past 3-4 years, which is followed by alcohol consumption for past 2-3 years and at last patients who had history of alcohol consumption from past 1-2 years. (Table 1)

Table 1: Age and gender wise distribution of study participants.

Variables		No. of cases
Age (years)	21-30 years	12 (24%)
	31-40 years	26 (52%)
	41-50 years	7 (14%)
	51-60 years	5 (10%)
Gender	Male	47 (94%)
	Female	3 (6%)

In the present study, the most common clinical feature recorded among study participants was of nausea and vomiting seen in 46 (92%) of patients, which was followed by jaundice reported among 43 (86%) of patients. Hepatomegaly was reported among 37 (74%) of patients, which was followed by signs of liver failure reported among 30 (60%) patients, followed by anorexia reported among 29 (58%) of patients. Splenomegaly was reported among 17 (34%) of patients, fever was reported among 13 (26%) of patients, abdominal pain was reported among 12 (24%) of cases and ascites was reported among 8 (16%) study participants. (Table 3)

Table 2: Distribution of study participants based upon clinical features.

Clinical features	No. of cases
Nausea and vomiting	46 (92%)
Jaundice	43 (86%)
Hepatomegaly	37 (74%)
Signs of liver failure	30 (60%)
Anorexia	29 (58%)
Splenomegaly	17 (34%)
Fever	13 (26%)
Abdominal pain	12 (24%)
Ascites	8 (16%)

DISCUSSION

In the present study we enrolled 50 patients who were aged from 21 to 59 years. The mean age of the enrolled patient with alcoholic liver disease was 36.42 ± 4.78 years. There was no patient in the present study who aged less than 18 years of age. Out of total patients diagnosed with alcoholic liver disease 94% were male and 6% were females. In the present

study, majority of the patients were in the age group of 31-40 years (52%) which is followed by 24% of the patients were in the age group of 21- 30 years followed by 14% of the patients were in the age group of 41-50 years and 10% of patients were in the age group of 51-60 years. Similar results were obtained in a study conducted by Chavan et al among patients of alcoholic liver disease and found that majority of the patients with alcoholic liver disease were in the age group of 30-40 years (9). Similar results were obtained in a study conducted by Nand et al among patients of alcoholic liver disease and found that male preponderance was highly prevalent. They reported similar mean age finding to the present study (10).

In our study majority of patients were farmers which is followed by employed at private service and daily wages workers. In the present study, according to the of alconol consumption majority of the patients were consumed alcohol intake more than 60 gm which is followed by patients who were consuming alcohol 50 - 60 gm in 24 hours and lastly patients who had history of alcohol consumption of less than 50 gm in 24 hours. On the basis of consumption, majority of the patients had alcohol consumption of more than five years which is followed by alcohol consumption for past 3-4 years, which is followed by alcohol consumption for past 2-3 years and at last patients who had history of alcohol consumption from past 1-2 years. Similar results were obtained in a study conducted by Pathak et al among patients of alcoholic liver disease and found that male preponderance was highly prevalent and majority of patients were farmers which is followed by employed at private service and daily wages workers (11). Similar results were obtained in a study conducted by Ray et al among patients of alcoholic liver disease and found that majority of the patients had alcohol consumption of more than 80 grams per day and also consumed poor quality of liquor for a mean duration 9 years and more (12).

In the present study, the most common clinical feature recorded among study participants was of nausea and vomiting seen in 46 (92%) of patients, which was followed by jaundice reported among 43 (86%) of patients. Hepatomegaly was reported among 37 (74%) of patients, which was followed by signs of liver failure reported among 30 (60%) patients, followed by anorexia reported among 29 (58%) of patients. Splenomegaly was reported among 17 (34%) of patients, fever was reported among 13 (26%) of patients, abdominal pain was reported among 12 (24%) of cases and ascites was reported among 8 (16%) study participants. Similar results were obtained in a study conducted by Mitra et al among patients of alcoholic liver disease and found that ascites was the most common finding followed by hepatic encephalopathy and upper gastrointestinal bleed (13). Similar results were obtained in a study conducted by Mendenhall et al among patients of alcoholic liver disease and found that in majority of patients ascites was the most common finding (14). Similar results were obtained in a study conducted by Khatroth S et al among patients of alcoholic liver disease and found that in majority of patients nausea and vomiting and jaundice, hepatomegaly, loss of appetite or anorexia and palpable splenomegaly are the most common findings (15).

CONCLUSION

We concluded from the present study that larger quantities of alcohol consumption for a longer duration of time result in high morbidity and mortalities. Alcoholic liver disease is not only a medical burden but also a social burden which leads to frequent hospitalization and unwanted out of pocket expenditure.

Abstract

Background: Thyroid disorders are reported in higher magnitude among general population, although its prevalence is not as high as prevalence of diabetes mellitus. Thyroid disorders are endocrine in nature as diabetes mellitus and various studies were conducted to find out correlation between both the disorders.

Material & Methods: Patients who were presenting with type 2 diabetes mellitus and confirmed with laboratory investigations and healthy controls were enrolled from outdoor and from ward by simple random sampling. Clearance from Institutional Ethics Committee was taken before start of study. Written informed consent was taken from each study participant.

Conclusion: We concluded from the present study that the patients of diabetes mellites had higher prevalence of thyroid dysfunction in comparison to the healthy controls enrolled in the study. We found suoclinical hypothyroidism was more common than clinical hypothyroidism.

Key words: thyroid dysfunction, diabetes mellitus, hypothyroidism, hyperthyroidism.

INTRODUCTION

Diabetes is a chronic disease in etiology and occurs when the pancreas does not produce enough amount of insulin or when there is resistance towards its action on the body (1). In 2014, WHO reports that 8.5% of adults who aged 18 years or above had diagnosed with diabetes. In 2016, WHO reports that diabetes was the directly responsible for 1.6 million mortality occurred worldwide. It was estimated that by the year 2030 diabetes will became seventh leading cause of mortality worldwide (2). The prevalence of non-communicable diseases is increasing compared to communicable diseases. Among the non-communicable diseases, diabetes mellitus is rapidly increasing globally and affecting all the age groups. (3). In India, the prevalence of diabetes is increasing and imposing challenges on health care infrastructure of the country (4).

The overall prevalence of diabetes reported by WHO was 8.7% among the age group of 20 and 70 years. This rising prevalence depends on various factors such as, sedentary lifestyles, rapid urbanization, unhealthy diets and substance use/abuse along with increasing life expectancy (5). Obesity and overweight are also the most important associated risk factors. The onset of diabetes can be prevented or delayed by life style and behavioral changes by taking healthy diet and routine physical activity (6). Thyroid disorders are reported in higher magnitude among general population, although its prevalence is not as high as prevalence of diabetes mellitus. Thyroid disorders are endocrine in nature as diabetes mellitus and various studies were conducted to find out correlation between both the disorders (7). Hence, we conducted present study to find out association between the thyroid disorders and type 2 diabetes mellitus.

MATERIALS & METHODS

The present prospective study was conducted at department of general medicine of our tertiary care hospital. The study duration was of one year from January 2018 to December 2018. A sample size of 200 was calculated at 95% confidence interval at 10%

acceptable margin of error by epi info software version 7.2. Patients who were presenting with type 2 diabetes mellitus and confirmed with laboratory investigations and healthy controls were enrolled from outdoor and from ward by simple random sampling. Clearance from Institutional Ethics Committee was taken before start of study. Written informed consent was taken from each study participant.

The data were collected by detailed history, general physical and clinical examination from each patient after taking the written consent. The hematological investigation was done for fasting and post prandial blood sugar, glycosylated hemoglobin (HbA1c) and thyroid profile. Patients who had chronic diseases such as cardiac diseases, liver and renal diseases, hypertension and cancer were excluded from the study. Data analysis was carried out using SPSS v22. All tests were done at alpha (level significance) of 5%, means a significant association present if p value was less than 0.05.

RESULTS

In the present study we enrolled 100 patients of diabetes mellitus who were aged from 27 to 58 years. The mean age of the enrolled patients was 42±5.6 years. In the present study we enrolled 100 healthy controls who were aged from 24 to 55 years. The mean age of the enrolled controls was 37±6.8 years. Out of total patients diagnosed with diabetes mellitus 59% patients were male and 41% patients were females. Out of total healthy controls 56% were male and 44% were females. On the assessment of BMI it was found that patients diagnosed with diabetes mellitus had mean BMI of 29.1±2.4 and controls had mean BMI of 28.5±3.1. On the assessment of TSH it was found that patients diagnosed with diabetes mellitus had mean TSH levels of 3.3±2.6 and controls had mean TSH levels of 3.2±1.8. On the assessment of FT4 levels it was found that patients diagnosed with diabetes mellitus had mean FT4 levels of 1.4±1.1 and controls had mean FT4 levels of 1.5±0.7. (Table 1)

Table 1: Demographic variables of study participants

Parameters	Diabetes group	Control group
Age (Mean ± SD)	42±5.6	37±6.8
Male	59 %	56 %
Female	41 %	44 %
BMI (Kg/m2)	29.1±2.4	28.5±3.1

In the present study, among total study participants it was found that, the prevalence of thyroid dysfunction among the type II diabetes group was 28% and among the control group was 16%. The prevalence of subclinical hypothyroidism among the among the type II diabetes group was 17% and control group was 11% (p>0.05). The prevalence of Clinical Hypothyroidism among the among the type II diabetes group was 8% and control group was 4% (p>0.05). The prevalence of subclinical hyperthyroidism among the among the type II diabetes group was 2% and control group was 1% (p>0.05). The prevalence of Clinical hyperthyroidism among diabetes group was 1% (>0.05) (Table 2).

Table 2: Distribution of types of Thyroid disorders among the study participants

Type of thyroid disorder	Diabetes group	Control group	p value
Subclinical hypothyroidism	17%	11%	>0.05
Clinical Hypothyroidism	8%	4%	>0.05
Subclinical hyperthyroidism	2%	1 %	>0.05
Clinical Hyperthyroidism	1%	0 %	>0.05
Total	28%	16%	

DISCUSSION

Diabetes is a chronic disease in etiology and occurs when the pancreas does not produce enough amount of insulin or when there is resistance towards its action on the body. Among the non-communicable diseases, diabetes mellitus is rapidly increasing globally and affecting all the age groups. Thyroid disorders are reported in higher magnitude among general population, although its prevalence is not as high as prevalence of diabetes mellitus. Thyroid disorders are endocrine in nature as diabetes mellitus

and various studies were conducted to find out correlation between both the disorders (8).

In the present study we enrolled 100 patients of diabetes mellitus who were aged from 27 to 58 years. The mean age of the enrolled patients was 42±5.6 years. In the present study we enrolled 100 healthy controls who were aged from 24 to 55 years. The mean age of the enrolled controls was 37±6.8 years. Out of total patients diagnosed with diabetes mellitus 59% patients were male and 41% patients were females. Out of total healthy controls 56% were male and 44% were females. Similar results were obtained in a study conducted by Palma et al among diabetes mellitus patients and found that the prevalence of thyroid dysfunction was reported to be 15%. However, majority of cases they found were of subclinical hypothyroidism which is followed by clinical hypothyroidism (9). Similar results were obtained in a study conducted by Fremantle et al among diabetes mellitus patients and found that the prevalence of thyroid dysfunction was reported to be 9%. Majority of cases they found were of subclinical hypothyroidism which is followed by clinical hypothyroidism (10). Similar results were obtained in a study conducted by Chuet cols et al among diabetes mellitus patients and found that the prevalence of thyroid dysfunction was reported to be 9%. Majority of cases they found were of subclinical hypothyroidism which is followed by clinical hypothyroidism (11).

In the present study, on the assessment of BMI it was found that patients diagnosed with diabetes mellitus had mean BMI of 29.1±2.4 and controls had mean BMI of 28.5±3.1. On the assessment of TSH it was found that patients diagnosed with diabetes mellitus had mean TSH levels of 3.3±2.6 and controls had mean TSH levels of 3.2±1.8. On the assessment of FT4 levels it was found that patients diagnosed with diabetes mellitus had mean FT4 levels of 1.4±1.1 and controls had mean FT4 levels of 1.5±0.7. Similar results were obtained in a study conducted by NHANES study among diabetes mellitus patients and found similar values of TSH and FT4 levels among diabetic patients (12). Similar results were obtained in a study conducted by Ramos AJS et al study among diabetes mellitus patients and found that the prevalence of thyroid dysfunction was reported to be 20%. Majority of cases they found were of subclinical hypothyroidism which is followed by clinical hypothyroidism (13).

In the present study, among total study participants it was found that, the prevalence of thyroid dysfunction among the type II diabetes group was 28% and among the control group was 16%. The prevalence of subclinical hypothyroidism among the among the type II diabetes group was 17% and control group was 11% (p>0.05). The prevalence of Clinical Hypothyroidism among the among the type II diabetes group was 8% and control group was 4% (p>0.05). The prevalence of subclinical hyperthyroidism among the among the type II diabetes group was 2% and control group was 1% (p>0.05). The prevalence of Clinical hyperthyroidism among diabetes group was 1% (>0.05). Similar results were obtained in a study conducted by Souza et al study among diabetes mellitus patients and found that the prevalence of thyroid dysfunction was reported to be 14%. Majority of cases they found were of subclinical hypothyroidism which is followed by clinical hypothyroidism (14).

CONCLUSION

We concluded from the present study that the patients of diabetes mellites had higher prevalence of thyroid dysfunction in comparison to the healthy controls enrolled in the study. We found subclinical hypothyroidism was more common than clinical hypothyroidism; however this difference was statistically non-significant. Since present study had small sample size, therefore, further large studies required for generalization of study results.

Dear Authors, Rajiv Kumar Saxena, Hemendra Bamaniya (Corresponding author), H.S. Bhuie

We are pleased to inform you that your Original Research Article (Title: Role of Nasal Douching in Chronic Allergic Rhinitis) has been accepted for publication in Tropical Journal of Ophthalmology and Otolaryngology.

We are planning to finalize and publish your article in the issue of April June 2019 (in Volume- 4, Issue 2 of 2019 will be published in next 2-3 weeks) of our Tropical Journal of Ophthalmology and Otolaryngology. We may ask you for any minor corrections if we found anything at drafting and finalizing the article.

We shall send Galley proof of article before publication. Kindly see the attachments for further processing.

Your accepted article no is: TJOO 2019-12

Date: 18th May 2019

Sub: Acceptance of Original Research Article for Publication in Print Journal- International Journal of Research and Review

Dear Sir,
We are pleased to inform you that your article entitled **"Serum Vitamin D levels in chronic Allergic Rhinitis"** has been accepted for publication under *Original Research Article* category in Vol.6; Issue 6; June 2019 Issue of International Journal of Research and Review. The article is contributed by Rajiv Kumar Saxena, Hemendra Bamaniya and H.S. Bhuie.
Corresponding author is Dr. Hemendra Bamaniya.

Best wishes to all authors/coauthors!

ORIGINAL ARTICLE

Comparison between Voice Handicap Index and Voice Symptom Scale by Subjective Analysis of Voice Disorders

[1]Hemendra Samariya, [2]Alok K Vaishnav, [3]Shashank Joshi, [4]Harbinder S Bhuie, [5]Rajiv K Saxena

ABSTRACT

Objective: Purpose of the present study was to use and compare two patient-derived scales voice handicap index (VHI) and voice symptom scale (VoiSS) for the assessment of the quality of life in patients of voice disorders and to assess their response to treatment.

Design: Longitudinal, cohort comparison study.

Setting: Department of Otorhinolaryngology, Maharana Bhupal Government Hospital, Udaipur, Rajasthan.

Participants: Fifty patients with a complaint of change in voice attended ear, nose and throat outpatient department at Maharana Bhupal Government Hospital and Rabindranath Tagore Medical College, Udaipur from 7th July 2010 to 30th June 2011.

Materials and methods: Two self-reported patients derived scale VHI and VoiSS were applied to all 50 patients of voice disorders both before as well as after treatment and compared the effect sizes of both the scales.

Result: Out of 50 cases, predominant cases included in the study were of malignant growth larynx (30%) followed by vocal nodule (18%). A total of 60% were male, and 40% were female. Maximum cases were of 41 to 60 years of age group (48%). Both the patient-derived scales VHI and VoiSS were found equally useful in assessing the quality of life in patients of voice disorders. Outcomes were similar in both the scales. The mean scores in both the scales before treatment were reduced to almost half after the respective treatment.

Conclusion: The result suggested that both the scales (VHI and VoiSS) are equally important as the results were highly correlated and no strong evidence was found to favor either of the scales. These scales are very useful in the assessment of the impact of voice disorders on patient's life and improvement in the quality of life after respective treatment as well as in assessing response to treatment.

Keywords: Dysphonia, Quality of life, Voice handicap index (VHI), Voice disorders, Voice symptom scale (VoiSS).

INTRODUCTION

Voice is a complex phenomenon that is produced by interaction among the respiratory, laryngeal and resonance sub-systems.[1]

The phonation or voice is produced when the air is expelled from the lungs through the glottis, creating a pressure drop across the larynx. The oscillations of vocal cords modulate the pressure and flow of the air through the larynx, and this modulated airflow is the main component of the sound of most voiced phones.

Describing the vocal function and evaluating the voice problems are, likewise, complex tasks.

Voice measurement can improve our understanding of voice production, helps us to identify links between laryngeal disorders and voice production, and document change with interventions. It is also an important part of all phonatory surgery.[2]

Voice measures are divided into three categories:

1. Patient scales
2. Perceptual evaluation
3. Measures

Patient Scales

- VHI
- VoiSS
- Voice Related Quality of Life (V-RQOL)
- Voice activity and participation profile (VAPP)
- Reflux symptom scale (RSI)
- Patient questionnaire of vocal performance (VPQ)
- Voice outcome survey (VOS)

Perceptual Evaluation

- Auditory perceptual scale
  - Grade, roughness, breathiness, asthenia, and strain (GRBAS)

b. Consensus auditory perceptual evaluation-voice (CAPE-V),
c. Vocal profile analysis (VPA)
- Visual perceptual scale
- Tactile perceptual evaluation

Measures

Measuring voice is accomplished using:
- Acoustic analysis,
- Aerodynamic assessment, and
- Source measures.

Dysphonia can be defined as an impairment of the speaking or singing voice. It arises from an abnormality of the structures and or functions of the voice production system and can cause bodily pain, personal communication disability or an occupational or social handicap. The etiology of dysphonia is multifactorial. Genetic and psychological factors may predispose an individual to voice disorders.[2]

There are so many acute and chronic variables which can precipitate dysphonia. These include occupational vocal demands, trauma, environment, medications, health problems and lifestyle choices. Dysphonia is as disruptive to quality of life as any other chronic disease like angina, sciatica and chronic sinusitis.[3] The communicative issues associated to dysphonia can lead to depression, social withdrawal, and occupational handicap.[4]

OBJECTIVE

The objective of the present study is to use and compare VHI and VoiSS for the assessment of the quality of life in patients with voice disorders and their response to treatment.

Voice Handicap Index

It is a voice-specific outcome, measures patients' disability from voice disorders.

The index consists of a 30-item questionnaire, and each statement is noted from 0 (never) to 4 (always) composing a total score from 0 to 120, the higher the standard score, the higher the VHI (Table 1).

Voice Symptom Scale

This scale is yet in progress.

VoiSS consists of 43 items on a five-point equal appearing interval scale that reflects the frequency of occurrence. The total score is 0 to 172 (Table 2).

The questions in VoiSS represent five aspects (or domains) of voice pathology-communication problems, throat infection, psychosocial distress, voice sound, and variability and phlegm.

MATERIALS AND METHODS

This study was carried out on 50 patients that came to Otorhinolaryngology OPD at Maharana Bhopal (M.B.) Hospital and R.N.T. Medical College, Udaipur from 7th July 2010 to 30th June 2011 with a clinical diagnosis of dysphonia.

All patients then underwent thorough history-taking, general physical examination, and uniformly documented detailed local examination.

The routine laboratory tests, viz. blood for Hb, TLC, DLC, ESR, urinalysis, sklagram soft-tissue neck lateral view, sklagram chest PA view were done in all cases.

An indirect laryngoscopic evaluation was performed in all cases. Direct laryngoscopy and histopathological examination were done in required cases.

Thus the clinical diagnosis was made of all the cases with voice problems. Then the 43-item questionnaire of VoiSS and 30-item questionnaire of VHI were applied to all patients. The results and scores of both the voice analysis tools (VoiSS and VHI) were then compared to each other.

All the patients under study were kept under follow up until the proper treatment of voice disorder was carried out. The follow-up period for the different patient was different as the treatment duration for all diseases is not the same.

The patients were assessed thoroughly again, and both the VHI and VoiSS questionnaire were reapplied to all the patients after treatment.

Only those patients who were able to complete the posttreatment questionnaire were included in the study. Laryngectomized and tracheostomized patients were excluded from the study.

The comparisons between pre and post-intervention VHI scores and pre- and post-intervention VoiSS scores as well as between VHI and VoiSS scores were carried out to assess the role of these scores in deciding treatment pattern for the voice disorders as well as in assessing the quality of life of patients of voice disorders.

The improvement in the quality of life following treatment of voice disorder was assessed using the difference between pre and post VHI and VoiSS score.

RESULTS

The maximum number of cases of dysphonia, we encountered was of malignant growth larynx followed by a vocal nodule, globus and so on, as plotted on the following table (Table 3).

Since the cases included in the present study were only those, who were able to complete our questionnaire

Table 1: Voice handicap index

S.No	Questionnaire	Score				
	Part I-F	0	1	2	3	4
1.	My voice makes it difficult for people to hear me.					
2.	People have difficulty understanding me in a noisy room.					
3.	My family has difficulty hearing me when I call them throughout the house.					
4.	I use the phone less often than I would like to.					
5.	I tend to avoid groups of people because of my voice.					
6.	I speak with friends, neighbors, or relatives less often because of my voice.					
7.	People ask me to repeat myself when speaking face-to-face.					
8.	My voice difficulties restrict my personal and social life.					
9.	I feel left out of conversations because of my voice.					
10.	My voice problem causes me to lose income.					
	SUBTOTAL _____					
	Part II-P					
1.	I run out of air when I talk.					
2.	The sound of my voice varies throughout the day.					
3.	People ask, "What's wrong with your voice?"					
4.	My voice sounds creaky and dry.					
5.	I feel as though I have to strain to produce voice.					
6.	The clarity of my voice is unpredictable.					
7.	I try to change my voice to sound different.					
8.	I use a great deal of effort to speak.					
9.	My voice is worse in the evening.					
10.	My voice "gives out" on me in the middle of speaking.

of VHI and VoSS and were supposed to come for the follow up till the intervention for their voice disorder completed, so the data of prevalence of voice disorders may be different than in present study.

In the present study, the prevalence of voice disorders was found to be more in male (60%) patients as compared to female (40%) patient.

Also, the prevalence of cancer larynx and laryngopharynx was found to be more in male and prevalence of globus was more in female patients.

Globus pharyngis, in most cases, is caused by inflammation of one or more parts of the throat, such as the larynx and/or hypopharynx, gastroesophageal reflux disorder, due to cricopharyngeal spasm, laryngo-pharyngeal reflux or oesophageal versatility.[7]

In a few cases, the cause of globus is unknown, and the symptoms may be attributed to a psychogenic cause, i.e., a somatoform or anxiety disorder. It has also been recognized as a symptom of depression, that responds to antidepressive treatment.[8]

Table 2: Voice symptom scale

S.No	Questionnaire	0	1	2	3	4
1.	Do you have difficulty attracting attention?					
2.	Do you get frustrated by your voice problem?					
3.	Do you have problems singing?					
4.	Do people ignore you?					
5.	Is your throat sore?					
6.	Are you able to shout?					
7.	Is your voice hoarse?					
8.	When talking in company do people fail to hear you?					
9.	Do you lose your voice?					
10.	Does your voice problem reduce your social life?					
11.	Are you able to read aloud?					
12.	How often do you worry about catching a throat infection?					
13.	Do you cough or clear your throat?					
14.	Do you have pains in the chest?					
15.	Do you have a weak voice?					
16.	Do you have problems talking on the telephone?					
17.	Do you feel miserable or depressed because of your voice problem?					
18.	Does it feel as if there is something stuck in your throat?					
19.	Do you have swollen glands?					
20.	Do you talk less than you normally would?					
21.	Are you embarrassed by your voice problem?					
22.	Do you find the effort of speaking tiring?					
23.	Does your voice problem make you feel stressed and nervous?					
24.	Do you have difficulty competing against background noise?					
25.	Are you unable to shout or raise your voice?					
26.	Are you able to ask for things in shops?					
27.	Does your voice problem put a strain on your family and friends?					
28.	Do you have a lot of phlegm in your throat?					
29.	Do you run out of air when you talk?					
30.	Does the sound of your voice vary throughout the day?					
31.	Do people seem irritated by your voice?					
32.	Do you have a blocked nose?					
33.	Do people ask what is wrong with your voice?					
34.	Does your voice sound creaky and dry?					
35.	Do you feel you have to strain to produce voice?					
36.	Do you find other people do not understand your voice problem?					
37.	Do you try to change your voice to sound different?					
38.	How often do you get throat infections?					
39.	Is your voice worse in the evening?					
40.	Does your voice 'give out' in the middle of speaking?					
41.	Do you feel annoyed when people ask you to repeat?					
42.	Does your voice make you feel incompetent?					
43.	Are you ashamed of your voice problem?					
	Total					

0 = Never, 1 = Occasionally, 2 = Some of the time, 3 = Most of the time, 4 = All of the time

A total of 44% of cases examined in the present study were having a history of smoking or alcohol intake.

Moreover, all case of cancer laryux and laryngopharynx were having a history of smoking or alcohol intake or both which significantly proves cigarette smoking and alcohol intake as the important risk factor of cancer larynx and laryngopharynx.[7]

A total of 24% of all cases in the present study were having a history of vocal abuse either due to occupation or due to habit.

All cases of the vocal nodule, vocal cord papilloma, and vocal polyp were having a history of vocal abuse, which is showing the relationship between vocal abuse and development of vocal nodule or polyp.[8] Though vocal cord papilloma is a viral disease and is not associated with vocal abuse, in our case there was a coincidental history of vocal abuse.

Majority of the cases (48%) included in this study were of the age group of 41 to 60 years and the rests were as shown in Table 4.

Table 3: Clinical diagnosis of patients with voice disorders

No.	Diagnosis	No. of cases	Percentage
1.	M.G. larynx	15	30%
2.	Vocal nodule	9	18%
3.	Globus pharyngis	6	12%
4.	M.G. pharynx	5	10%
5.	Laryngitis	5	10%
6.	Pharyngitis	3	6%
7.	Vocal cord palsy	2	4%
8.	Vocal cord polyp	1	2%
9.	Vocal cord papilloma	1	2%
10.	Puberphonia	1	2%
11.	Goitre	1	2%
12.	Acute bronchial Asthma	1	2%
	Total	50	100%

Table 5: Presenting complaints of the patients

S.No.	Presenting complaints	No. of cases	Percentage
1.	Change in voice	35	70
2.	Difficulty in breathing	03	06
3.	Difficulty in swallowing	05	10
4.	Stridor	04	08
5.	Neck swelling	03	06
6.	Total	50	100

The presenting complaint of most of (70%) patients included in the present study, was the change in voice. The change in voice varied from simple harshness in laryngitis to hoarseness in carcinoma larynx. Six percent of the patient came with the complaint of neck swelling associated with dysphonia. 10% of patient were having to present complains of difficulty in swallowing, 8% were having stridor, and 6% patients came with complaints of difficulty in breathing (Table 5).

VHI scores of all the patients both before and after treatment were noted, and also the differe nce between them was calculated (Table 6 and Fig. 1).

5.	51–60	12	24
6.	61–70	07	14
7.	71–80	01	02
	Total	50	100

Table 6: Pre- and post-treatment VHI score

	Pre-treatment VHI score			Post-treatment VHI score			
Total count	Mean	Standard deviation	Standard error	Mean	Standard deviation	Standard error	Mean of difference
50	89.7	26.54	3.75	49.96	29.315	4.14	42.14

Table 7: Pre- and post-treatment VoiSS score

	Pre-treatment VoiSS score			Post-treatment VoiSS score			
Total count	Mean	Standard deviation	Standard error	Mean	Standard deviation	Standard error	Mean of difference
50	119.28	37.98	5.37	83.16	35.32	4.99	58.12

A significant difference between pre- and post-treatment VHI score was found which shows the improvement in the quality of life of the patient after treatment of voice disorder.

Similarly, scores of VoiSS both before and after treatment were also noted and statistical analysis was done (Table 7 and Fig. 2).

In case of VoiSS questionnaire also, a similar type of scores found showed improvement in the quality of life of the patient after treatment of the voice disorder.

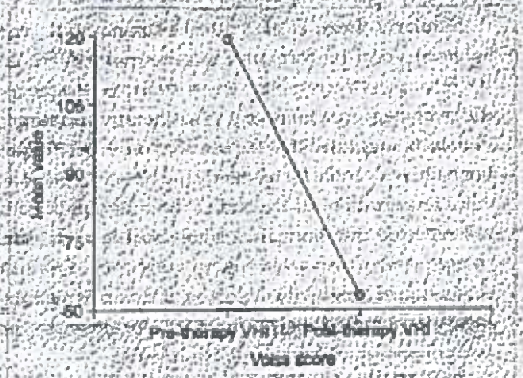

Fig. 2: Plot of mean sections of pre and post therapy VoiSS score

VoiSS score; more is the improvement in the quality of life of the patient.

CONCLUSION

In the present study, the results of both VHI and VoiSS were similar and highly correlated, and the comparative study did not favor any of the scale more for the evaluation purpose.

Thus the study showed that both VHI and VoiSS are important tools to assess the disability caused by voice disorders and also very useful to measure the functional outcomes of medical, behavioral and surgical treatment of voice disorders. These scores help the clinician and the patient to compare various treatment options. The improvement in the quality of life of the patient as well as the effectiveness of various voice intervention can be assessed using these scales.

ABSTRACT

Background: Tympanoplasty, also called eardrum repair, refers to surgery performed to reconstruct a perforated tympanic membrane (eardrum) or the small bones of the middle ear. Eardrum perforation may result from chronic infection or, less commonly, from trauma to the eardrum.

Objective: The Objective of the study is to evaluate the surgical outcomes of tympanoplasties with and without mastoidectomies in terms of graft uptake and hearing improvement.

Methods: A total of 58 patients undergoing tympanoplasties with and without mastoidectomy were included and followed up for a period of one year.

Results: There was no significant difference in the surgical outcomes of both the surgeries in terms of graft uptake and hearing improvement. In inlaid technique Ballast Rule of 3 thumb application enables the actual hearing benefit of the patient.

Conclusion: There is no difference in related to outcome. The addition of cortical mastoidectomy to tympanoplasty did not improve the outcome of surgeries done for mucosal type of chronic suppurative otitis media.

KEY WORDS: Cortical Mastoidectomy, Tympanoplasty, Ballast Rule.

INTRODUCTION

Tympanoplasty, also called eardrum repair, refers to surgery performed to reconstruct a perforated tympanic membrane (eardrum) or the small bones of the middle ear. Eardrum perforation may result from chronic infection or, less commonly, from trauma to the eardrum.

The tympanic membrane of the ear is a three-layer structure. The outer and inner layers consist of epithelium cells. Perforations occur as a result of defects in the middle layer, which contains elastic collagen fibers. Small perforations usually heal spontaneously. However, if the defect is relatively large, or if there is a poor blood supply or an infection during the healing process, spontaneous repair may be hindered. Eardrums may also be perforated as a result of trauma, such as an object in the ear, a slap on the ear, or an explosion [1]. The purpose of tympanoplasty is to repair the perforated eardrum, and sometimes the middle ear bones that consist of the incus, malleus, and stapes. Tympanic membrane grafting may be required. If needed, grafts are usually taken from a vein,

or fascia (muscle sheath) tissue on the lobe of the ear [2]. Synthetic materials may be used if patients have had previous surgeries and have limited graft availability. The mastoid is a honeycomb cavity in the temporal bone, which lies directly behind the ear and is connected to the middle ear space. When a hole arises in the eardrum due to previous injury or infection, or when a long-standing infection persists with tissue in the middle ear or mastoid, mastoid surgery often becomes necessary to alleviate this infection. This part of the procedure is called mastoidectomy. Surgery for tubotympanic type of chronic suppurative otitis media is the commonest otological surgical procedure in our country [3].

This study discusses the various pre-operative factors which play a major role in the post-operative success of two various surgeries – myringoplasty and cortical mastoidectomy with type 1 tympanoplasty. The hearing benefit is determined by Air bone gap closure and also subjective evaluation of hearing is done by applying Belfast rule of thumb.

MATERIALS AND METHODS

This Prospective study was conducted at RNT medical college and attached M B hospital, Udaipur, Rajasthan from Dec 2009 to Dec 2011. Study involves total 56 patients attending ENT OPD with mucosal disease at Our hospital for a period of one year and the patients were followed up for a period of one year. Among them, 6 patients did not turn up for follow up and they were excluded from the study.

Inclusion criteria: Patients between 15 to 50 years of both sexes, after elimination of focal sepsis, having either wet or dry ears and pure tone audiometry showing conductive hearing loss.

Exclusion Criteria: Patients with congenital or acquired abnormalities of ear, unsafe ear, undergone ear surgeries previously and with pure tone audiometry showing mixed and sensorineural hearing loss were excluded from the study.

Methodology: Minimum duration of discharge for the patients under study was 1year and maximum was 15 years. Minimum duration of hearing impairment was 6 months and maximum was 10 years. For all patients, under study with wet ears, ear swabs were taken from middle ear and for patients with culture positive results, treated with specific antibiotics prior to surgery.

All cases were admitted, pre-operative examination done under microscopy, subjected to endoscopic eustachian tube evaluation (those with normally looking pharyngeal end of eustachian tube orifice were taken up for study) and hearing assessment done with tuning fork tests and pure tone audiogram. All patients were informed about their need for a follow up period of one year. Informed written consent to undergo surgery was obtained from all patients. Mastoid shaving and local preparation was done in the ward prior to surgery. All cases were done under GA. Premedication and local infiltration was done for all cases.

Group A: About 25 patients with dry ear for more than 6 weeks and with only conductive hearing loss, were subjected to myringoplasty and considered as Group A. About 13 patients with unilateral disease and 12 patients with bilateral disease were taken up for study. For patients with bilateral disease, worse ear was taken up for surgery. All patients were taken up for surgery under GA. Trans canal approach was followed in 21 cases and in 4 cases with narrow external auditory canal, post aural approach was followed. 4 quadrant local infiltration was given with 2% xylocaine with adrenaline premixed solution. Temporalis fascia graft harvested by a separate incision over supra auricular region for patients done through trans-canal approach & in patients done through post aural approach, graft was harvested via the same incision. Temporalis fascia graft kept by underlay technique. All cases were followed up for 3,6 months and one year for graft uptake and postoperative hearing evaluations done at 3,6 months and one year. Results of hearing benefit, compared with pre-op and post-op air bone gap and for unilateral disease Belfast rule of thumb applied.

Group B: About 25 patients with wet ear and with no active infection as per microbiological report & with conductive hearing loss were subjected to cortical mastoidectomy with type 1

tympanoplasty and considered as Group B. About 15 patients with unilateral disease and 10 patients with bilateral disease were taken up for study. For patients with bilateral disease, worse ear was taken up for surgery.

All patients were taken up for surgery under GA. Post-aural approach was followed in all cases. Post aural incision made, temporalis fascia graft harvested through the superior aspect of the incision as the first step, incision deepened and mastoid cortex exposed. Pinna retracted anteriorly, incision made in the posterior canal wall skin from 6 o'clock to 12 o'clock position and tympanomeatal flap was elevated. Granulations if present in the tympanum were removed, mobility of ossicular chain were checked. Mastoid cortex was drilled out in all cases, patency established. For, about 21 patients granulations noted in antrum removed and in 4 patients antrum found free of disease. For all patients, temporalis fascia graft kept by underlay technique, tympanomeatal flap repositioned and post-aural wound closed in layers. All cases were followed up for 2, 6 months and 1 year for graft uptake and post-operative hearing evaluations done at 3, 6 months and 1 year. Results of hearing benefit, compared with pre-op and post-op air bone gap and for unilateral disease, Belfast rule of thumb applied.

Even though socio-economic status does influence the disease, all the patients attending RNT Medical College and M B Hospital Hospital belongs to lower, socio-economic group. Hence this parameter is not included in this study.

RESULTS

Total number of cases registered in this study was 56 patients, who came to the ENT Department with Mucosal disease. Among them 6 patients did not turn up for follow up and hence they were not included in the study.

The overall graft take up rate in both the surgeries was 88.33%. The overall hearing benefit was 90%, excellent with < 10dB ABG in 51.67% and Good with < 20dB in 38.33%. There was no postoperative complications, deterioration in hearing or sensorineural hearing loss in all 50 patients.

In Group A ,15 were females & 10 were males, 13 patients had unilateral and 12 had bilateral disease, 20 had medium sized central perforation and 05 had subtotal perforation. 10 had good pre-op Air bone gap of 10 to 20 dBHL 15 patients had a fair pre-op Air bone gap of 20 to 30 dBHL.

1. Overall graft take up rate was 86.6%.

2. Otoscopic evaluation of 20 patients with medium sized perforation at the end of 2 months, revealed 15 to be intact, 5 residual perforation in the antero - inferior quadrant. In 5 patients with subtotal perforation 3 were intact, 1 with residual perforation & 1 grafts got rejected because of post-op wound infection. Otoscopic examination at the end of 6months & 1 year revealed – for all 20 patients with medium size perforation, tympanic membrane was intact and out of 5 patients with subtotal 2 were with residual perforation & 1 with rejection of graft. Hence the size of the perforation does have a role in graft take upirate. This is statistically significant by applying chi square test with p value < 0.05.

3. In 10 patients with good pre-op ABG, the post-op ABG was excellent. In 15 patients with fair pre-op ABG, the post-op ABG results were, excellent in 9, good in 8 and fair in 3 patients accounting for 46.66% in excellent, 40% in good and 13% in fair groups. By applying Chi square test, these results are statistically significant. Hence, for the patients with lesser pre-operative Air bone gap have a better post-operative hearing.

4. When Belfast rule of thumb was applied to 13 patients with unilateral disease, 10 of them with medium sized perforation, felt subjectively better and out of 3 of them with subtotal perforation, 2 felt better & 1 patient felt hearing same as the pre operative status. These results are statistically significant with p value<0.05, implies that Belfast rule of thumb interpret the post-operative hearing benefit in a better way than the Air-bone gap ,which tells about only the technical success.

5. The correlation coefficient between the duration of discharge and the pre-op ABG is 0.4172 and that between the duration of hearing impairment with pre-op ABG is 0.3821 and is statistically significant. The correlation coeffi-

-ent between the duration of discharge and the post-op ABG is 0.4544 and that between the duration of hearing impairment with post-op ABG is 0.4489 and is statistically significant, implies that the patients with lesser duration of discharge and hearing impairment had better post-operative hearing than the patients with longer duration of disease and hearing impairment.

6. The other parameters, such as age, sex, weight does not have influence on the outcome of results in this study.

7. The type of approach does not have a significant p value with graft intake in this study. Applying chi square test, the Pearson value is 0.

In Group B, 17 were females & 8 were males, 15 patients had unilateral and 10 had bilateral disease. 18 had medium central perforation and 07 had subtotal perforation, 08 had good pre-op Air bone gap of 10 to 20 dBHL, 17 patients had a fair pre-op Air bone gap of 20 to 30 dBHL.

1. Overall graft take up rate was 96%.

2. The relationship between graft take up rate and size of the perforation is statistically significant by applying chi square test with person value of 0.02535.

Otoscopic evaluation of 15 patients with medium sized perforation at the end of 2 months, revealed 14 to be intact, 1 residual perforation in the antero-inferior quadrant. In 07 patients with subtotal perforation, 05 were intact, 2 with residual perforation. Otoscopic examination at the end of 6 months & 1 year revealed – for all 18 patients with medium size perforation, tympanic membrane was intact and out of 07 patients with subtotal 3 were with residual perforation. Hence the size of the perforation do have a role in graft take up rate even when cortical mastoidectomy is done along with repair of tympanic membrane.

3. In this study, out of 18 patients with medium sized perforation, 8 had a good & 17 had fair pre-op ABG. Out of 07 patients with subtotal perforation, 6 patient had good & 01 had fair pre-op ABG, implies that 85.71 % of the patients with subtotal perforation had pre-op ABG of 20 to 30 dB.

4. Out of 25 patients included in this procedure -re, 50% had excellent, 50% had good &10% had fair post-op ABG. Those with medium sized perforation had better results than those with subtotal perforation.

5. On comparison of pre-op ABG & post-op ABG, all 8 patients with good pre-op ABG improved to excellent, out of 17 with fair ABG, 3 were excellent, 12 were good and 2 were fair post-operatively. This result is highly statistically significant with pearson value of 0.00006

6. Graft intake in 4 patients with disease free antrum mucosa is 100%.

7. Out of 25 patients, 21 patients had disease in the antrum & 4 had a healthy antrum. 77.85% of the patients with healthy antrum and 9.5% of the patients with diseased antrum had good pre-op Air bone gap 30.5% with diseased and 22.2% with healthy antrum had fair preop Air bone gap.

8. In patients with healthy antrum, the post-op ABG was excellent in 88.9% and 66.7% of the patients

with diseased antrum had a good ABG post-operatively.

9. On applying Rellfast rule of thumb to 15 patients with unilateral disease, 83.3% had better hearing, implies the post-operative hearing benefit better than assessment with Air bone gap.

10. The correlation coefficient between the duration of discharge and the pre-op ABG is 0.3803 and that between the duration of hearing impairment with pre-op ABG is 0.3776. The correlation coefficient between the duration of discharge and the post-op ABG is 0.3794 and that between the duration of hearing impairment with pre-op ABG is 0.3729 and are statistically significant, implies that the patients with lesser duration of discharge and hearing impairment had better post-operative hearing than the patients with longer duration of disease and hearing impairment.

11. The other parameters, such as age, sex, weight does not have influence on the outcome of results in this study.

DISCUSSION

Analysis of 50 cases undergone surgery for [illegible]

same is compared with similar and related studies available in literature.

1. Graft Take Up Rate: The overall graft take up rate in Myringoplasty in this study was 86.6%, which is within the range to the studies available. The graft take up rate in various studies were [Table 1].

Table 1: Graft take up rate [1].

Study	No of cases	year	Graft take up rate
Gibb, Cleary R.M [5]	345	1982	91.60%
Black, PJ Wormald [3]	261	1995	78%
Raj A Vidit [2]	50	1999	84%
Kotecha et al [7]	107	1999	82.20%
Tseng, Mishira et al [1]	104	2001	94.60%
Kageyama et al [6]	190	2001	82.30%
Alberra et al [2]	85	2008	86%

The graft take up rate in Cortical mastoidectomy with type 1 tympanoplasty is 90% which is also within the range to the studies available in literature [Table 2].

Table 2: Graft take up rate [2].

Studies	No of cases	Graft take up rate
Tseng, Mishira et al [1]	147	94.20%
Adnan, saleem et al [2]	85	92.95 %
Alberra et al [2]	100	91%
Rabi CM et al [2]	135	90.40%

2. Graft Failure Rate: Graft failure rate in various studies were [Table 3].

Table 3: Re-perforation Rate % [1].

Studies	Re-perforation Rate %
Alberra et al [2]	7 to 21
Vartiainen et al [14]	10.6
Adnan, saleem et al [2]	7.05

In this study, in myringoplasty series the rate of residual perforation is 5.7% and the rate of rejection of graft is 6.7%. The probable cause of residual perforation is the slippage of the graft from its position and the cause for rejection is the post operative infection of the operated site, which is same as the reason cited by the study of Vartiainen et al and Kotecha et al [7,14] Study of Alberra et al also includes the efficiency of the surgeon and the surgical techniques [2].

3. Pre-operative Hearing: In this study the pre operative pure tone average in Myringoplasty series was between 30 to 40 dB with average type 1 tympanoplasty series between 30 to 55 dB with average being 42.16 dB. As the perforation size increases, the preoperative hearing threshold also increases – this is consistent with the study conducted by Mehta et al, Bhusal et al Nepal A Bhandary et al, Kageyama et al, Alberra et al and Saeed et al [1,2]

4. Post Operative Hearing Benefit: Hearing improvement in various studies quoted in literature were [Table 4];

Table 4: Hearing Improvement [2,3].

Study	Hearing improvement
Adnan et al [2]	85.88%
Khan et al [1,2]	84.90%
Raj A Vidit et al [2]	68%
Kotecha et al [7]	67%

In this study, the overall post operative hearing benefit based on Air bone gap was 90% with <10 Db in 51.67% and <20db in 38.33%. As hearing benefit is better assessed with the subjective evaluation, in this study we have applied Belfast rule of thumb in patients with unilateral disease. In 23 patients with unilateral disease in Myringoplasty series, 95.7% felt significant improvement in hearing and 4.3% felt no improvement. In 18 patients with unilateral disease in Mastoidectomy with type 1 tympanoplasty series, 83.3% felt significant improvement in hearing and 16.7% felt no improvement.

CONCLUSION

From Our study we Would like to conclude that the success of Myringoplasty in terms of graft uptake and hearing improvement is better in patients with lesser duration of disease, less preoperative Air bone gap and with medium sized perforations when compared to subtotal perforations. The success of Cortical mastoidectomy with type tympanoplasty in terms of graft uptake and hearing improvement is better in patients with lesser duration of disease and less pre-operative Air bone gap.

ABSTRACT

Objectives: The objective of our study was to examine the aerobic bacteriological profile and antibiotic sensitivity pattern to locally available antibiotics in chronic suppurative otitis media (CSOM) in Rajsamand district of Rajasthan state in India.

Materials and methods: This prospective study was conducted in the department of otorhinolaryngology, Aranya Institute of Medical Sciences, Rajsamand for a period of one year from February 2017 to February 2018. Aural swabs were taken on the first day of attendance of the patients to ENT OPD before any local medication was given to the patient, using sterile cotton wool swabs and sterile ear specula and sent for culture and sensitivity.

Results: A total of 150 cases of CSOM were selected for the study out of which 109 cases were of unilateral CSOM and 41 cases were having bilateral disease. Thus, a total of 191 swabs were taken for analysis. Out of 191 swabs processed, microbial growth was seen in 176 samples while 15 samples showed no growth. 121 (68.75%) samples showed mono-microbial growth while 55 (31.25%) samples showed poly-microbial growth. The peak incidence of CSOM was found in the age group 31-45 years (34.66%) followed by age group 16-30 years (27.33%). Females (62%) were more commonly affected than males (38%) and the female: male ratio was 1.6:1. *Pseudomonas aeruginosa (38.63%) was the most commonly isolated bacterial pathogen followed by staphylococcus aureus (35.22%) and Klebsiella sp. (10.22%).*

Conclusion: A thorough and precise knowledge of the etiological agents causing CSOM and their antimicrobial susceptibility is of essential importance for an effective and efficient treatment and thus in further prevention of both complications and development of antibiotic resistance which is becoming more common now a days.

Keywords: Chronic suppurative otitis media, antibiotic resistance, staphylococcus aureus, Amikacin

INTRODUCTION

Chronic suppurative otitis media (CSOM) is a major problem globally since prehistoric times with higher incidence in developing countries because of poor socio-economic status and lack of health education.[1]

CSOM is a long standing infection of a part or whole of the middle ear cleft. Clinically, CSOM is divided into two major types: Tubotympanic CSOM i.e. 'Safe' or 'Benign' type of CSOM and Atticoantral i.e. 'unsafe' or 'dangerous' type of CSOM.[2]

CSOM is found to be the single major cause for conductive deafness (66.3%) and it is also responsible for 1.5% of speech disorders.[3]

The indiscriminate, haphazard and half hearted use of antibiotics and poor follow up of the patients have resulted in

persistent changes in the bacteriological pattern of the disease, the advent of new antimicrobials, anti-inflammatory and anti-histamine agents make an evaluation of bacterial flora of CSOM important. [4]

The objective of our study was to examine the bacteriological profile and antibiotic sensitivity pattern to locally available antibiotics in CSOM.

MATERIALS AND METHODS

This prospective study was conducted in the department of otorhinolaryngology, Ananta Institute of Medical Sciences, Rajsamand for a period of one year from February 2017 to February 2018.

Aural swabs were taken on the first day of attendance of the patients to ENT OPD before any local medication was given to the patient, using sterile cotton wool swabs and sterile ear speculs. The collected samples were enclosed in airtight plastic tubing and then transported to the microbiology test laboratory. The samples were always taken before cleaning/suctioning the ear canals of the excess purulent exudates. Samples from bilaterally discharging ears were collected separately. The material was inoculated on Sheep Blood agar, Mac Conkey's agar, Chocolate agar, Robertson's Cooked meat broth for aerobic and anaerobic bacteria. The swabs were incubated for 48 hr and 72hr. Organisms were identified using standard procedures. [5] Antimicrobial sensitivity testing for aerobic isolates was carried out by Kirby Bauer disc diffusion method on Muller Hinton agar. Results were interpreted in accordance with central laboratory standards institute guide-lines. [6]

RESULTS

A total of 150 cases of CSOM were selected for the study out of which 109 cases were of unilateral CSOM and 41 cases were having bilateral disease. Thus, a total of 191 swabs were taken for analysis.

Out of 191 swabs processed, microbial growth was seen in 176 samples while 15 samples showed no growth. 121 (68.75%) samples showed mono-microbial growth while 55 (31.25%) samples showed poly-microbial growth.

In present study, age of the patients ranges from 10 months to 73 years. The peak incidence of CSOM was found in the age group 31-45 years (34.66%) followed by age group 16-30 years (27.33%). Females (62%) were more commonly affected than males (38%) and the female: male ratio was 1.6:1. (table.1)

Microbiological profile of isolates from patients of CSOM and their antibiotic sensitivity pattern is depicted in table.2 and table.3 respectively.

Table.1 Age wise distribution of patients with CSOM.

S.No.	Age group (years)	Number	Unilateral	Bilateral	Mono-microbial	Poly-microbial	Sterile	Total
1.	10-15	23	11	12	22	9	4	35
2.	16-30	41	34	7	33	12	3	48
3.	31-45	52	44	8	38	17	5	60
4.	46-60	20	12	8	11	13	4	28
5.	61-75	14	8	6	4	4	2	20
	Total	150	109	41	121	55	15	191

Table.2 microbiological profile of aerobic isolates from patients of CSOM.

S.No.	Type of organism	Number of samples	Percentage
1.	Pseudomonas aeruginosa	68	38.63
2.	Staphylococcus aureus	62	35.22
3.	Klebsiella sp.	18	10.22
4.	Proteus mirabilis	17	09.65
5.	E.coli	8	04.54
6.	Enterococcus faecalis	3	01.70
	Total	176	100

DISCUSSION

CSOM is a long standing infection of a part or whole of the middle ear cleft. Clinically, CSOM is divided into two major types: Tubotympanic CSOM i.e. 'Safe' or 'Benign' type of CSOM and Atticoantral i.e. 'unsafe' or 'dangerous' type of CSOM. [2]

The definitive treatment of CSOM is by surgery (tympanoplasty and/or mastoidectomy), nevertheless, initial treatment by ear toilet and ototopical agents is necessary to prepare the ear for surgery. The selection of local or systemic antibiotic for therapy depends greatly on the type of the organism isolated in such cases.

In present study, microbial growth was seen in 176 (92.14%) samples out of 191 swabs used. 15 samples (7.8%) showed no growth. The culture results are found correlated with previous studies. [7-11] Negative cultures can be attributed to Non-bacterial growth, Anaerobic growth, Prior-antibiotic therapy and/ or Presence of antimicrobial enzymes i.e. lysozyme alone or in combination with immunoglobulins that suppress the bacterial growth. [4,10]

121 (68.75%) samples showed mono-microbial growth while 55 (31.25%) samples showed poly-microbial growth. Our study is correlated with Rama Rao et al. (1980) [9] found equal incidence of mixed and pure culture and Barnak et al. (1972) [12] found predominance of mixed culture.

In present study, most commonly affected age group was 31-45 years (34.66%) followed by age group 16-30 years (27.33%). In most of the earlier studies, the most commonly affected age group is 0-30 years. [13-16] The reason for high prevalence in higher age group in present study may be because of low socioeconomic status and poor awareness of the patients in villages near the hospital.

In the present study, Pseudomonas aeruginosa (38.63%) was the most commonly isolated bacterial pathogen followed by staphylococcus aureus (35.22%) and klebsiella sp. (10.22%).

Pseudomonas is the predominant cause of CSOM in tropical region does not usually inhabit the upper respiratory tract, its presence in the middle-ear cannot be ascribed to an invasion through eustachian tube and it should be considered as secondary invader gaining access to the middle-ear via tympanic membrane perforation. [17] Proteus mirabilis was seen in 9.65%% of the cases and Escherichia coli were isolated from 4.5% cases, and these findings were similar to the reports in earlier studies. [14,16]

In the present study the most effective antibiotic against Pseudomonas aeruginosa was found to be Vancomycin (94.11%) followed by amikacin (86.76%), piperacillin+Tazobactam, ceftazidime, netilmicin, Gentamicin, ceftriaxone and ciprofloxacin. This finding was corroborated by studies of numerous other authors. [13,18,19]

Staphylococcus aureus was found to be the second most common organism in the present study. The antimicrobial susceptibility pattern of Staphylococcus

aureus revealed highest sensitivity to piperacillin+tazobactam (88.70%) followed by amoxicillin+ clavulanate (77.41%), Vancomycin (75.80%), ceftriaxone & ceftazidime (70.96%), Netilmicin (67.74%) and Amikacin (61.29%) and least sensitivity to quinolones. In case of Klebsiella sp, Proteus, E.coli and Enterococcus faecalis-ceftriaxone, Amikacin and piperacillin with Tazobactam were found to be equally effective. These findings are in accordance with previous study done by Gulati et al (1997). [9]

CONCLUSION

A thorough and precise knowledge of the etiological agents causing CSOM and their antimicrobial susceptibility is of essential importance for an effective and efficient treatment and also in further prevention of both complications and development of antibiotic resistance which is becoming more common now a days.

ABSTRACT: Marjolin's ulcer is a malignant tumour developing in a chronic skin lesion (burn scar, vaccination scar, non-healing wound etc.). The majority of cases reported are squamous cell carcinoma. Surgery remains the first treatment of choice (resection with 2cms. safety margin of healthy skin for primary squamous cell carcinoma Marjolin ulcers and 2.5cms. safety margin for recurrent cases). Recurrence after surgery and regional lymph node metastasis are not uncommon (17% & 30% respectively).We presents a case report and literature review of Recurrent Marjolin's Ulcer with regional Lymph Node Metastasis. Marjolin's ulcer should be considered as a significant post-burn complication; it should be treated with full emphasis on adequate local clearance and regular follow up for many years; if not treated adequately, it may lead to complicated recurrence.

KEY WORDS: Marjolin's Ulcer, Recurrent, Lymph Node Metastasis.

INTRODUCTION: Marjolin's ulcer is a malignant tumour developing in a chronic skin lesion (burn scar, vaccination scar, non-healing wound etc.).[1] The majority of cases reported are squamous cell carcinoma but other type of malignancy such as basal cell carcinoma, malignant melanoma, liposarcoma, osteosarcoma, and fibrosarcoma can also be seen although rare.[2] The incidence of burn scar undergoing malignant transformation has been reported to be 0.77-2 %.[3]

CASE REPORT: A 22 year old male was presented to our surgical department with exophytic ulcerated growth of size 7x7 cm. near angle of right scapula. He had a past history of burn over anterior chest wall, back and left arm 12 years ago that healed completely by conservative management. Approx. 11 years after initial insult, the patient developed an ulcer on the back over burn scar. It gradually increased in size to become exophytic growth of size 12x12cms. No regional lymph node enlargement was noted at that time. Whole of the ulcer with a 2 cm. margin of healthy skin was excised. The defect in skin was closed by partial thickness skin graft. Histopathological examination of the excised tissue was suggestive of poorly differentiated squamous cell carcinoma.

8 months after surgery & skin grafting, the patient came with exophytic ulcerated growth of size 7x7 cm. near angle of right scapula. It was fixed to underlying muscles of back.

Patient was also having another fungating growth in left axilla which was 6x6 cms. in size, fixed to underlying structures causing restriction of movements at shoulder. Serous discharge was present from axillary growth. There was no vascular or neurological impairment present in left upper limb. Biopsy from axillary growth was positive for squamous cell carcinoma.

LITERATURE REVIEW: The eponym "Marjolin's ulcer" was derived from French surgeon Jean Nicholas Marjolin in 1828 who observed and classified cellular change in burn skin and coined the term "ulcere cancroide".[4] The skin lesion underlying development is predominantly burn scar (75%), traumatic non healing wound (8%), venous stasis ulcer (6%), pressure ulcer (3%) and other e.g. Frost bite, vaccination scar .[1]

The latency period is inversely proportional to patient's age at the time of skin injury. In chronic Marjolin's ulcer it ranges from 20-40 year as transformation from non-healing wound to malignant disease is slow. The average time lag between the burns and subsequent malignant ulceration is 19 years. [5] In acute Marjolin's ulcer it occurs within few weeks to one year.[1] Average age at diagnosis of Marjolin's ulcer is in 5th decade of life with a range of 18-84 years.[2] It is seen more frequently in males as compare to females with ratio of 3:1.[2] Most commonly it is located on lower extremities (53%), upper extremities (18%), trunk (12%), face and nape (5%), scalp (9%).[4]

Aetiology of Marjolin's ulcer is not yet clear. Many hypotheses have been suggested. Slow healing and scar instability characterized by chronic irritation and the induction of constantly proliferating epidermal unit have been blamed. Repeated cycle of healing and breakdown, wound that never healed and application of irritant medication are all result in reduced ability to withstand carcinogens.[6] As a result of constant breakdown of ulcer, a nutritional deficiency develops, owing to release of toxins by autolysis and heterolysis of scar. This yields an epithelium that is unable to withstand the carcinogens produced by skin because of excessive heat and radiation. [7] Ultraviolet rays are also found to be associated with Marjolin's ulcer. On histological examination of sun damaged skin, dyskeratosis and vacuolated keratinocytes known as sun burn cell are seen. Marjolin's ulcer least frequently founds on trunk which is not frequently exposed to sunlight. [8] It has also been suggested that relatively avascular scar tissue act as immune privileged site that allows the tumour to resist body defences against foreign cell.[6]

Scar tissue acts as a barrier for the tumours, if we release this barrier, the virulent spread of the tumour will be permitted.[8] Regional lymph node metastasis and recurrence after surgery is not uncommon. Metastasis to regional lymph nodes is seen in 30% of cases and local recurrence occurs in 17% of patients. The median interval to recurrence after surgery is 15 months. Locoregional recurrence is more common in female patients and those with high-grade tumours.[9] Poorly differentiated squamous cell carcinomas have a tendency to spread to lymph nodes earlier. Squamous cell carcinomas resulting from the Marjolin's ulcer have a much greater tendency to metastasize than squamous cell carcinomas resulting from the other causes [10].

Various studies suggested that all chronic wound should be closed surgically either by skin graft or skin muscle flap. Large wound should not be left for secondary intention healing. Burn scar from childhood should be carefully monitored; biopsy of any suspected lesion should not be delayed. At present no standard treatment for Marjolin's ulcer is suggested. Surgery remains the first treatment of choice. Marjolin's ulcer should be excised with a 2 cm. margin of normal healthy tissue, which may necessitate amputation with lesion involving joint space or deep local extensive invasion. Although classically 2cm safety margin is still widely used for resection of primary squamous cell carcinoma Marjolin ulcers, 2.5cm safety margin is better for

CASE REPORT

HUGE VULVAL ELEPHANTIASIS OF UNKNOWN AETIOLOGY

Anjali Sethi[1], Deepak Sethi[2]

HOW TO CITE THIS ARTICLE:
Anjali Sethi, Deepak Sethi. "Huge Vulval Elephantiasis of Unknown Aetiology". Journal of Evolution of Medical and Dental Sciences 2014; Vol. 3, Issue 13, March 31; Page: 3324-3329, DOI: 10.14260/jemds/2014/2288

ABSTRACT: Genital Elephantiasis is an important medical problem in the tropics; usually affects young and productive age group and is associated with physical disability and mental anguish. It is one of the bizarre & nipping diseases and has a long history of worldwide distribution. Most of the reported cases occur as an end result of lymphatic obstruction due to various diseases like Filariasis, sexually transmitted diseases (LGV & Donovanosis) as well as malignancies. Few cases may remain of unknown etiology. We are reporting a case of huge vulval elephantiasis, etiology of which remained unknown.

KEYWORDS: Elephantiasis, Lymphatic Obstruction, Vulval.

INTRODUCTION: The word 'Elephantiasis' was originally used to describe elephant like appearance of legs. The term was subsequently used to describe the similar enlargement of arm, chest, breast, vulva, penis & scrotum.

Genital Elephantiasis is an important medical problem in the tropics; usually affects young and productive age group and is associated with physical disability and mental anguish. It is one of the bizarre & nipping diseases and has a long history of worldwide distribution. Most of the reported cases occur as an end result of lymphatic obstruction due to various diseases like Filariasis, sexually transmitted diseases (LGV & Donovanosis) as well as malignancies.[1]

CASE REPORT: A 35 years old female was presented with a huge mass arising from right labium majus for 2 years. She noticed a small swelling over her vulva at right labium majus 2 years back. The swelling gradually increased in size over period of 2 years to reach the size of approximately 60*60 centimetres. (Figures No. 1, 2, 3). The whole mass hanged from labium to reach up to knees.

The history did not reveal any symptoms related to Filariasis, sexually transmitted disease or any other disease. She had a history of surgery for excision of similar but small swelling from the same labia 5 years ago. No documental record related to previous surgery was present with patient.

The mass was non-tender, firm in consistency and had rugosities all over its surface with ulcerations at some places. The skin over supra – pubic region was also involved. The other labium was normal. Both lower limbs were normal. Inguinal Lymph nodes were not palpable. General Physical examination revealed anemia and otherwise normal.

Pre-operative investigations showed mild anemia and FNAC from the mass showed chronic non-specific inflammation. Examination of nocturnal skin prick blood sample for microfilariae was negative, Mantoux test was negative and Complete Blood Counts did not show any Eosinophilia or Lymphocythemia. After full investigations, patient was posted for operation.

After spinal anesthesia patient was placed in lithotomy position. Whole of the mass from vulva & also from supra – pubic region was excised (total weight of the mass was approx. 8 kilograms) (Figure No. 5). The vulva was reconstructed and wound was primarily closed over a

DOI: 10.14260/jemds/2014/2288

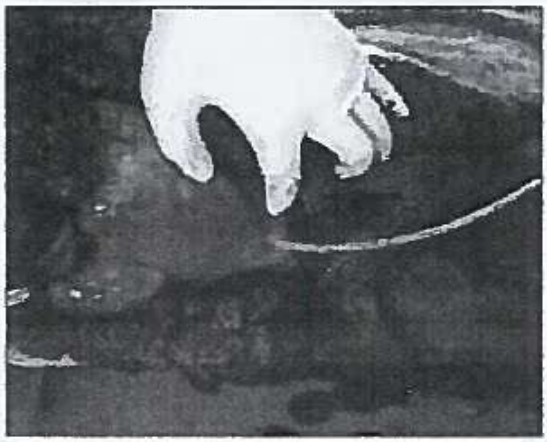

Fig. 3 : Left Labium Majus is Normal

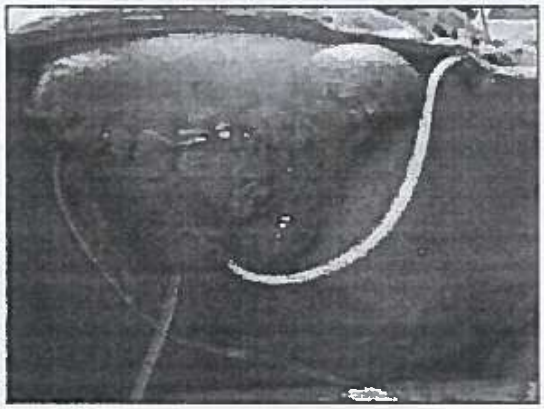

Fig. 4: Immediate Post-Operative photograph

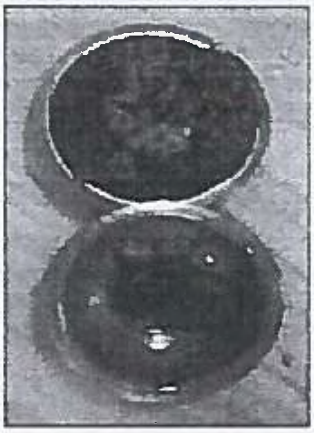

Fig. 5: Resected Elephantiasis Tissue specimen weighing approx. 8 kilograms

edema, sclerosing fibrosis of subcutaneous tissue, elephantiasis and chronic genital ulceration. It is often associated with ano-rectal complications including fistulae & strictures both in men & women.

Donovanosis is chronic progressive destructive, granulomatous infection of superficial tissue of the genital region, caused by Calymmatobacterium granulomatis. Lymphedema of genital region is one of the long term complications. Clinically Donovanosis induced elephantiasis is characterized by firm, pedunculated, lobular swelling. It affects predominantly the labia majora & the clitoris.

Various treatment modalities have been described for genital elephantiasis which includes compression therapy, drugs & surgery. Basic principle of the treatment is complete removal of all affected tissue by surgery, and drugs for causative organism.[6]

Compression therapy is not practical for lymphedema of genitalia; but minor swelling can be treated by support hosiery.

Drugs:

LGV– Doxycycline 100 mg. twice daily for prolonged period of approx.13 months.

Donovanosis– Azithromycin 1 gm on first day followed by 500 mg once daily or Co-trimoxazol (Trimethoprim 80 mg & Sulphamethaxazol 400 mg) two tablets twice daily for 10-14 days.

Filariasis– Diethyl Carbazine is the drug of choice.

Bypass procedures include omentum pedicle, Skin Bridge anastomosing lymph nodes to vein; and most recently lympho-venous anastomosis with aid of microscope. However, long term results of all these techniques are poor.

Reduction procedures include removal of subcutaneous elephantoid tissue and closure of wound either by preservation of overlying skin flaps or by free skin graft or rotational flaps. Labial reduction is easily achieved by wide elliptical excision with single suture line.[6]

CONCLUSION: Genital elephantiasis is a significant medical problem and persons affected may become a major burden to their families & community. At present surgery is only effective option for patients in whom the disorder is disabling, persistent and psychological devastating.

Abstract

Penile cutaneous horn is a horn like hyper-keratotic lesion over penis which is an unusual site and a rare case. We report a case of cutaneous horn of penis in age of 20 years which is also a rare presentation in this age group.

Key words: Cutaneous Horn, Penile Cutaneous Horn, Penile Horn

Manuscript Received: 20th Sept 2015, **Reviewed**: 4th Oct 2015
Author Corrected: 10th Oct 2015, **Accepted for Publication:** 14th Oct 2015

Introduction

Cutaneous horns are also known as cornucutaneum, which are unusual keratinous skin tumors with the appearance of horn. This is clinically appears as conical projection above the surface of the skin [1]. Although the cutaneous horn may develop over a normal skin, these more often develop over some pre-existing skin conditions like warts, keratosis, nevi, trauma, burns, lupus vulgaris, and even on an epithelioma[2]. Cornucutaneum (cutaneous horn) is a well-defined cone-shaped lesion with hyper-keratotic features. This type of lesion mostly found on exposed skin [3]. Cutaneous horns occur rarely on the penis. The incidence of the lesion is very low, with only 30 cases reported in 25 years [4]. Disease may be benign in 42%-56%, premalignant in 22%-37%, or frankly malignant in 20%-22% of patients [5].

Case Report

BREAST CANCER: IS OBESITY A RISK FACTOR?

Anjali Sethi[1], Deepak Sethi[2], Dinesh Kumar Barolia[3]

ABSTRACT

Most epidemiological studies established obesity as an important risk factor for breast cancer. It is one of the few risk factors that women can modify. Now-a-days breast cancer is considered to be a life-style disease. The relation of obesity to breast cancer is complex one. Obesity is found to be associated with increased risk of cancer in post-menopausal women, but relation is reverse in pre-menopausal women. In these patients, obesity increases risk due to enhanced oestrogenic activity in obese females. Apart from it, other factors like Insulin-like Growth Factor (IGF-1), Leptin has also been involved. Due to big breasts in obese females there is delay in seeking medical attention, delay in diagnosis, poor response to surgery, chemotherapy, radiotherapy and associated complication during treatment. We study the effect of obesity (Weight, BMI, WHR) as a risk factor in occurrence of breast cancer in local population of Southern part of Rajasthan in India. We found no significant association between obesity and increased risk of breast cancer in local population of this region where women are multiparous, physically active and usually do not use exogenous hormones.

INTRODUCTION

Breast cancer is a malignancy of breast that is common in women and rare in men. Because breast is a superficial organ, it can be easily accessed by both patients and doctors. As the incidence of breast cancer increases, significant advances have been made in development of early detection method, less radical primary therapy, use of radiation and chemotherapy which have saved significant number of lives.

The quality of life in India is improving with improvements of socio-economic status. As the life expectancy increases, the cancer burden to society also increases. Apart from curative modalities, we must also think about preventive policies as an essential step. Definitive etiology of breast cancer has eluded the researchers. Breast cancer is now considered as a lifestyle disease. Lots of factors such as nutrition, lifestyle, high fat intake, age of menarche, age of first pregnancy, being overweight, use of HRT, age of menopause have been incriminated.

Breast cancer is considered to be a consequence of affluence and being overweight. Excess of adipose tissue leads to increased circulating oestrogen.

Obesity may further add insult to injury because lipid is more prone to oxidative damage as compared to protein and carbohydrate. In present study, we planned to find out association between obesity and breast cancer in local population of Southern part of Rajasthan in India.

INCIDENCE

Breast cancer is a global disease. Incidence of breast cancer is continuously rising in last few decades. It accounts for 33% of all female cancer and is responsible for 20% cancer related death in women. It also shows a widespread geographical distribution. There is many fold variation in incidence and mortality among different countries. In UK incidence was 74.4/1,00,000 in 2003, where as in South Korea it was 2.6/1,00,000 (Cancer Statistics 2003). In USA 2,11,300 new cases were diagnosed in 2003 with mortality of 39,800, which were raised to 2,32,000 new cases with mortality of 44,000 in 2012.

In India it has now become the first most common cancer in women population, way ahead of cervical cancer. It accounted for 25.9% of all female cancer in 2008; figure was raised to 27% in 2012. In India 1,15,000 new cases were diagnosed in 2008 with a mortality of 5,300, which raises to 1,45,000 new cases and mortality of 70,000 in 2012.[1] For the year 2015, there would be an estimated 1,55,000 new cases of female breast cancer and about 76,000 women in India are expected to die due to disease.[2]

METHODS AND MATERIAL

In present study, we studied 50 clinico-pathologically diagnosed patients of breast cancer. Diagnosis was based on detailed history, clinical examination, diagnostic modalities like mammography, USG and confirmed by FNAC and Tru-Cut Biopsy. Obesity was measured by body weight (Kg), Body Mass Index (BMI-Weight/Height.^{2} Kg/mt.^{2}) and Waist-to-Hip Ratio (WHR-Waist circumference-to-hip circumference ratio WC/HC). Waist circumference was measured just above the level of lateral iliac crest below lowest rib, and hip circumference under inferior rim of pubic symphysis in midline.

Received: 02/10/2015 *Revised: 23/10/2015* *Accepted: 23/10/2015*

ABSTRACT

Polyorchidism is a very rare congenital anomaly, less than 200 cases reported in literature. Triorchidism is commoner in polyorchidism, mostly extra testes found in left side. We report a case of 47 year old patient with incidental finding of third testis during inguinal hernia operation.

Key words: Polyorchidism, Polyorchism, Triple Testes, Orchiectomy, Rare.

INTRODUCTION

Polyorchidism is an uncommon congenital anomaly that is defines by presence of more than two testes in a man. The supernumerary testes may be present in scrotum or in inguinal canal or even intra-abdominally. It is a very rare congenital disorder, with fewer than 200 cases reported in medical literature (Bergholz R *et al.*; 2009). Polyorchidism is frequently associated with additional urological pathologies such as undescended testis, inguinal hernia, testicular torsion, hydrocoele, malignancy and infertility (O'Sullivan DC*et al.*; 1995), (Spranger R*et al.*; 2002).

CASE REPORT

We report a case of triple testes, an incidental finding during left inguinal hernia operation. A 47 year old male patient came to hospital with complaint of swelling in left inguinal region. Patient was diagnosed as a case of left indirect inguinal hernia. On clinical examination of scrotum both testes were present but left testis was smaller than right. After investigations, patient was posted for surgery under spinal anaesthesia. Intra-operatively it was found that spermatic cord contained two separate vas deferenses, one was connected to testis in scrotum and the other testis present in the inguinal canal (Figure-3). Orchiectomy was done of inguinal testes. Hernioplasty was done for inguinal hernia. Later on, ultra-sonic examination of right side showed presence of single testis on right side.

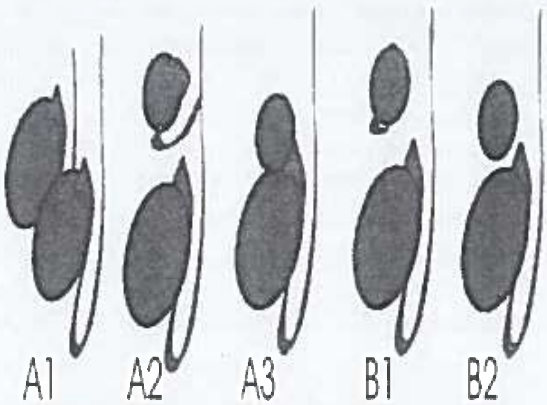

Figure 1- Classification (Dr. Matt A. Morgan *et al.*).

penile cutaneous horns are associated with an underlying malignancy[8,9].

Recently, several studies indicated that immune-histochemical expression of p16ink4a may be used not only as a marker of high-risk HPV infection, but also on differential diagnosis of penile epithelial abnormalities and precancerous lesions. Earlier data showed strong association of HPV with high-grade squamous cell carcinoma, whereas well-differentiated SCC subtypes were not HPVrelated. Chaux et al. Have published a study designed to seek an immune-histochemical profile that can be helpful in the classification and differential diagnosis of penile epithelial abnormalities and precancerous lesions[10].

Conclusion

Penile cutaneous horn is a rare case.Penile cutaneoushorn is a clinical diagnosis which is made on the basis of morphological appearance. Horn can be associated with benign or malignant condition. True diagnosis is proved after histopathological examination of tissue. We report this case of penile cutaneous horn with benign histopathology.

Abstract

Penile cutaneous horn is a horn like hyper-keratotic lesion over penis which is an unusual site and a rare case. We report a case of cutaneous horn of penis in age of 20 years which is also a rare presentation in this age group.

Key words: Cutaneous Horn, Penile Cutaneous Horn, Penile Horn.

Introduction

Cutaneous horns are also known as cornucutaneum, which are unusual keratinous skin tumors with the appearance of horn. This is clinically appears as conical projection above the surface of the skin [1]. Although the cutaneous horn may develop over a normal skin, these more often develop over some pre-existing skin conditions like warts, keratosis, nevi, trauma, burns, lupus vulgaris, and even on an epithelioma[2]. Cornucutaneum (cutaneous horn) is a well-defined cone-shaped lesion with hyper-keratotic features. This type of lesion mostly found on exposed skin [3]. Cutaneous horns occur rarely on the penis. The incidence of the lesion is very low, with only 30 cases reported in 25 years [4]. Disease may be benign in 42%-56%, premalignant in 22%-37%, or frankly malignant in 20%-22% of patients [5].

Case Report

We report a case of cutaneous horn at unusual site over penis. A twenty one year old male presented in hospital with conical shape hard swelling over ventral surface of penis. He noticed the lesion one year back. Before one year he was having the complaint of phimosis. Therefore he was operated circumcision. After two months of circumcision he develops the lesion. The lesion was gradually increased in size. When he came to hospital, lesion was conical in shape, hard in consistency, over ventral surface of penis and near about three centimeter in size. Horn was surgically excised with free margine. Histopathology of tissue at base of cutaneous horn shows hyperplastic squamous epithelium with marked hyper keratosis. There was no evidence of malignancy. This patient discharged without any complication with satisfactory result. In follow up patient was satisfied with surgery and having no complain.

Discussion

Cutaneous horn (synonyms: Cornucutaneum; Cornuhumanum) is a conical, hyper-keratotic protrusion that often resembles like an animal horn. The term "cutaneous horn" is not a true diagnosis. It is named after morphologic appearance like animal horn. To this date just >150 cases have been reported in the literature [4].The factor which leads to these patients developing penile horn is unclear. The roles of chronic irritation, phimosis, surgical trauma and radiotherapy that have been implicated in penile horn formation have also been found to predispose to carcinoma penis [1,6]. Cutaneous horn may be benign, premalignant or malignant. The etiology of penile cutaneous horn remains uncertain. The earliest documented case of cutaneous horn, or cornucutaneum, of an elderly Welsh woman in London who was displayed commercially as an anomaly of nature in 1588 [6]. The first case report of penile cutaneous horn was published in 1854[7]. The European Association of Urology guidelines on penile cancer they consider penile cutaneous horn as a premalignant lesion and approximately one-third of

This variant results from incomplete longitudinal division of the genital ridge and the proximal portion of the mesonephric duct. In type D, complete longitudinal duplication of the genital ridge and mesonephric duct occurs, with resultant complete duplication of testes, epididymides, and vas deferens. This type may be associated with an ipsilateral duplicated ureter and is the least common (John B. Amodio *et al.;* 2004).

It is believed to result embryologically from an abnormal division of the genital ridge (Woodward PJ *et al.;* 2003).Embryological theories responsible for polyorchidism include

i. degeneration of parts of the mesonephric components;
ii. duplication of the genital ridge; or
iii. division of the genital ridge.

There is an increased risk of malignancy if supernumerary testicles are detected (Ahlfeld F *et al.;* 1880).

Differential diagnosis: Possible differential considerations include scrotal hernia, bilobed testicle, crossed testicular ectopia, testicular tumour (Dr. Matt A. Morgan *et al.*).

Management: Because polyorchidism is very uncommon, there is no standard treatment for the condition. Prior to advances in ultrasound technology, it was common practice to remove the supernumerary testicle (Leung, A. K.; 1988). Several cases have been described where routine follow-up examinations conducted over a period of years showed that the supernumerary testicle was stable (Bergholz R *et al.*; 2009).

ABSTRACT

Breast cancer is the most common site specific cancer in women. Lots of etiological factors have been suggested regarding its causation. The risk is influenced by obesity, parity, exogenous and endogenous hormones, exposure to chemicals and radiation and many more. Various studies suggest that as HDL-C seems to be cardio protective, it is also protective for breast cancer. Serum HDL-C levels are found to be low in breast cancer patients. We studied this hypothesis in local population of Southern Rajasthan and nearby region to see if low serum HDL-C is associated with increased risk of breast cancer. We studied serum HDL-C level in 50 female patients of breast cancer along with their menopausal status and compared it to their respective controls. We found that breast cancer patients had significantly low level of serum HDL-C and presented in advanced stage of cancer. It supports that low serum HDL-C level is associated with increased risk of breast cancer. So one should think about those dietary and lifestyle measures, which maintain high serum HDL-C level so that it might become preventive measure for breast cancer.

INTRODUCTION

Breast Cancer is the most common site specific cancer in women and a leading cause of death due to cancer between 40-45 years of age. It has now become a global disease. It accounts for 33% of all female cancer and 20% of cancer related death in women.

The exact cause of breast cancer is not known but sex hormones, both endogenous and exogenous play an important role. Exposure to radiation and chemicals can also stimulate the onset of disease.[1] The risk of breast cancer is also influenced by dietary fat intake, obesity, parity, duration of breast feeding, family history and socio-economic status.[2] Breast cancer is considered to be consequences of high fat consumption.

There may be chemical carcinogen in fatty fried diet and altered bacterial flora in intestine leads to increased production of carcinogenic substances. Serum lipid profile is an important marker of dietary fat intake.[2] Various studies indicate that plasma triglycerides and LDL-C levels were found to be significantly elevated among breast cancer patients.,[3] but HDL-C level were observed to be significantly low as compared to control.[1,4,5] It raises a question that HDL-C seems to be protective in breast carcinogenesis.

Serum HDL-C levels are found to be low in breast cancer patients. We studied this hypothesis to see if low serum HDL-C is associated with increased risk of breast cancer.

CL–Confidence Limit
SR-BI–Scavenger receptor class B type I.

METHOD AND MATERIAL

We studied 50 patients of breast cancer. Patients were diagnosed on basis of detailed history, clinical examination, mammography, USG, FNAC, and Tru-Cut biopsy. Lifestyle parameters like socio-economic status, age of menarche, menopausal status, use of oral contraceptives, hormone replacement therapy, etc., were also evaluated.

HDL (HDL-C) was estimated in venous blood samples of patients. Blood sample of 50 controls were also analyzed for HDL-C. Controls were those females who were not suffering from breast cancer, but fell in same age group. HDL-C was detected in lab by direct homogenous assay method.

Females who presented in stage I and II were included in early stage and those in stage III and IV were included in advanced stage.

Abstract

Penile fracture is a rare surgical emergency. Penile fracture involved the rupture of corpus cavernosum and may be associated with rupture of corpus spongiosum or urethra. We report a case of a 22-year old man presenting with penile swelling and pain, with retention of urine after getting a trauma during sexual intercourse. After exploration in emergency, we found that there was isolated rupture of corpus spongiosum with urethra, both corpus cavernosum were intact. We did repair of the ruptured urethra and corpus spongiosum. In follow-up, the patient did not present any complications such as distortion of penis and erectile dysfunction.

KEY WORDS: Penile fracture, penis, corpus spongiosum, urethra, urethral injury

Introduction

Penile fracture is an uncommon urological emergency.[1] Penile fracture is a disordering of the tunica albuginea of one or both corpus cavernosum owing to blunt damage to the erect penis.[2] There is immediate loss of erection state, with large hematoma and deformation. There may be microscopic hematuria and urethral bleeding when corpus spongiosum ruptured along with urethra. This occurs in 10%–20% of cases.[3,4] Penile fractures typically present with a "cracking" sound, rapid detumescence of the penis and often pain, swelling, and ecchymosis.[5]

Case Report

We report a case of a 22-year old man who came to emergency with complaint of penile swelling with pain and per urethral bleeding. He gave history that, during sexual intercourse, he got trauma, then rapid loss of erection, penis became flaccid, penile pain, and bleeding per urethra. On physical examination, patient built was good. There was penile discoloration, swelling of penis and scrotum, and bleeding per urethra. Penis was tender, flaccid, and edematous. Patient was operated in emergency operation theater under anesthesia. Subcoronal circumferential degloving incision was given, and hematoma was drained. There was isolated rupture of corpus spongiosum along with urethra. After per urethral catheterization, urethra was repaired; then ruptured corpus spongiosum was repaired. Edematous foreskin was excised, and wound approximation was done. Patient was treated with broad spectrum antibiotics. Patient was discharged without any complication. In follow-up, Foleys Catheter was removed after third postoperative week. On last follow-up, he had normal erectile function, but he developed stricture urethra. He advised and explained intermittent self-urethral dilation.

Discussion

Penile fracture is the rupture of one or both of the tunica albuginea, the fibrous coverings that envelope the penile corpora cavernosa. It is caused by rapid blunt force to an erect penis, usually during vaginal intercourse or aggressive masturbation.[6] It sometimes also involves partial or complete rupture of the urethra or injury to the dorsal nerves, veins, and arteries.[7] Penile fractures account for approximately one case in 175,000 emergencies in emergency department visits.[8] There are 1,642 published cases in the literature.[1]

Figure 1: Fracture penis at the time of admission.

Figure 2: Drainage of hematoma.

Figure 3: Visible Foleys catheter through ruptured corpus spongiosum and urethra.

A 2014 study of accident and emergency records at three hospitals in Campinas, Brazil, showed that woman on top positions caused the greatest risk with the missionary position being the safest. The research conjectured that, when a woman is on top, she usually controls the movement, and her entire body weight lands on the erect penis. She is not able to interrupt movement when the penis suffers a misaligned penetration. Conversely, when the man is controlling the movement, he has better chances of stopping the penetration thrusts in response to pain, minimizing harm to himself.[9]

Early conservative treatment with cold applications, pressure dressings, catheterization, anti-inflammatory drugs, antibiotics, and erection suppressing drugs is now replaced with immediate surgical repair. Surgical repair of penile fracture was first described by Fetter and Gartman in 1936.[8] Since the early surgical repair reduces the complication of fracture, it is now the gold standard for treatment of penile fractures.[2-10]

Conclusion

Penile fracture is a rare surgical emergency. Isolated corpus spongiosum rupture along with urethra is a very rare condition. A complete physical examination and clinical history

required to diagnose penile fracture because patient present with different history. Early diagnosis and surgical intervention reduces the complication and increases the chances of full recovery.

PRIMARY GRYNFELTT'S LUMBAR HERNIA- AN UNCOMMON OCCURRENCE

Deepak Sethi[1], Anjali Sethi[2]

[1]Consultant Surgeon and SS (Surgery), Department of Surgery, RNT Medical College, Udaipur, Rajasthan.
[2]Associate Professor, Department of Surgery, Ananta Institute of Medical Sciences and Research Centre, Kaliwas, Rajsamand, Rajasthan.

ABSTRACT

BACKGROUND

Lumbar Hernia is an uncommon occurrence. It may occur through superior or inferior lumbar triangle. Hernia through superior lumbar triangle is more common. Treatment of lumbar hernia is essentially surgical with mesh repair, which may be done by open or laparoscopic techniques. Surgical management requires skill and expertise. We report a case of Lumbar Hernia through superior triangle (Grynfeltt's). A 57 years old lean and thin patient presented with swelling in left loin on coughing. Diagnosis was confirmed by ultrasonography. Hernia was repaired by on-lay application of polypropylene mesh. Patient was asymptomatic at follow-ups.

HOW TO CITE THIS ARTICLE: Sethi D, Sethi A. Primary Grynfeltt's lumbar hernia- an uncommon occurrence. Journal of Evolution of General Surgery and Laparoscopy 2017; Vol. 3, Issue 1, Jan-June 2017; Page: 1-3

BACKGROUND

Lumbar Hernia is an uncommon occurrence. A surgeon may come across with these hernias on a very few occasions in his life time. Lumbar Hernias account for approximately 2% of all abdominal wall hernias. Lumbar Herniation may occur through superior lumbar triangle (Grynfeltt's Hernia) or inferior Lumbar Hernia (Petit's Hernia). Lumbar Hernias may be congenital or acquired. Acquired hernias may be primary or secondary. We present a case of Primary Lumbar Hernia through superficial lumbar triangle.

CASE REPORT

A 57-year-old lean and thin male patient was presented to surgical outdoor with history of swelling on left side of his back for last 1 year. Swelling appeared while coughing or straining only and disappears after coughing. Swelling was smaller and asymptomatic initially. It gradually increased in size. He had no history of trauma or any surgical intervention at and around the local area.

On physical local examination, patient had slight retraction over left loin and a globular swelling appeared just below twelfth rib while coughing. On deep respiration, there was further retraction at loin and then a swelling measuring approximately 6 cm × 8 cm appeared on coughing. Swelling disappeared a few moments after coughing (Fig. 1).

Vital parameters and General Physical Examination were within normal limits except that patient was lean and thin with poor built and muscle mass. On ultrasonography, a defect of approximately 2 cm × 4 cm was observed in the muscular planes of left lumbar region below the twelfth rib. Rest of the examination was within normal limits. All routine investigations were within normal limits. So, decision of patient to be post for open hernioplasty was taken.

After informed risk consent, patient was given general anaesthesia and placed in right lateral position. Transverse incision was given below twelfth rib over the defect. After dissection of subcutaneous tissue, a defect of size approximately 2 cm × 4 cm was found in the muscular planes of superior lumbar triangle (Fig. 2). On exploration of the defect, a hernial sac was found. Hernial sac was reduced and defect in the muscular planes was closed with silk suture. A large on-lay polypropylene mesh was placed over muscles and was fixed on to the periosteum of twelfth rib superiorly, iliac crest inferiorly and to the muscles on medially and laterally and thus tension free mesh repair was done (Fig. 3). Post-operative period was uneventful. Suture removal was done on eighth post-operative day. Patient was asymptomatic at follow-ups.

ABSTRACT

BACKGROUND

Prostate, a genital organ, secretes fluid, seminal plasma, the possible function of which is to provide nutrition to the sperms and serve as their vehicle during ejaculation. Prostate is of great clinical importance because of its affinity for inflammatory, congestive, hyperplastic and neoplastic diseases. Majority of instances of prostatic pathology are manifested by derangement of urination owing to the intimate anatomical relationship between urinary bladder and prostate. We studied serum TSH Levels in patients of BPH and CA prostate and its relation with skeletal metastasis.

This descriptive study was aimed to study any correlation between Serum TSH level and bone metastasis in patients with Prostate carcinoma.

MATERIALS AND METHODS

This descriptive study was conducted at Rabindranath Tagore Medical College and Maharana Bhupal Government Hospital, Udaipur, Rajasthan in the Department of Surgery. A non-statistical sample size of 50 patients suffering from benign prostatic hyperplasia or prostate cancer was taken as per convenience. The patients were divided into 2 groups, 25 patients of BPH based on serum PSA estimation (control) and 25 patients of prostate cancer based on serum PSA estimation (test). Preoperative estimation of serum TSH and serum PSA was done in all the patients. All the patients were operated (TURP or palliative TURP). The results of serum TSH, serum PSA, and Gleason score were then analysed and a relation between increasing levels of serum TSH, serum PSA, and Gleason grade was sought based on exploratory data analysis (EDA).

RESULTS

Serum PSA level in most of the BPH patients was found to be within normal limit and serum TSH level in all of the BPH patients was found to be within normal limits. Only in 8% cases of Prostate carcinoma patients had very high PSA level (>100 ng/mL) as well as increased serum TSH level and it was associated with Gleason score 8 (high-grade tumour) and skeletal metastases. Further statistical/epidemiological studies are required for confirmation of these findings.

CONCLUSION

Only in 8% cases of Prostate carcinoma patients had a very high PSA level (>100 ng/mL) as well as increased serum TSH level, and it was associated with Gleason score 8 (high-grade tumour) and skeletal metastases. Further statistical/epidemiological studies are required for confirmation of these findings.

Majority of instances of prostatic pathology are manifested by derangement of urination owing to the intimate anatomical relationship between urinary bladder and prostate.

Prostate specific antigen (PSA) is a glycoprotein that is a serine protease. Its function may be to facilitate liquefaction of semen, but it is a marker for prostatic disease. It is measured by an immunoassay. The normal upper limit of PSA is about 4 ng/mL. Men with locally confined prostate cancer usually have serum PSA levels < 15 ng/mL. Its level in men with metastatic prostate cancer usually increased to > 30 ng/mL.

Human TSH on the other hand is a glycoprotein that contains 211 amino acids residue, plus hexoses, hexosamines and sialic acid. The biologic half-life of human TSH is about 60 min. The normal secretion rate is about 110 µg/day. The average plasma level is about 2 µIU/mL, which is produced

We studied serum TSH Levels in patients of BPH and CA prostate and its relation with skeletal metastasis.

MATERIALS AND METHODS

This descriptive study was conducted at Rabindranath Tagore Medical College and Maharana Bhupal Government Hospital, Udaipur, Rajasthan in the Department of Surgery.

A non-statistical sample size of 50 patients suffering from benign prostatic hyperplasia or prostate cancer was taken as per convenience.

The diagnosis was made by a combination of history, detailed clinical examination including digital rectal examination (DRE) and lymph node examination, radiological films of chest and pelvis and serum PSA levels. Serum TSH was estimated in all the patients.

The Patients were divided into 2-Groups of 25 each-

- Group A: 25 patients of BPH based on serum PSA estimation (control)
- Group B: 25 patients of prostate cancer based on serum PSA estimation (test).

Preoperative estimation of serum TSH and serum PSA was done in all the patients. All the patients were operated (TURP or palliative TURP). Postoperatively tissue biopsy was histopathologically examined in all the cases and grading was done based on the Gleason Scoring System.

The resultant data of serum TSH, serum PSA, and Gleason score were then analysed and a relation between increasing levels of serum TSH, serum PSA, and Gleason grade was sought based on exploratory data analysis (EDA).

RESULTS

A Total of 50 patients were studied, of which 25 were BPH Patients and 25 were CA Prostate. Age distribution of our patients was as per Table 1.

Most of the cases of BPH patients belonged to rural population i.e., 64% and 36% belonged to urban population. Most of the cases of Prostate carcinoma patients belonged to rural population i.e., 76% and 24% belonged to urban population.

In BPH, all of the patients had complaints of sensation of incomplete emptying of urinary bladder, weak urinary stream and hesitancy (100%) followed by frequency, intermittency and nocturia (92%), urgency (88%), dysuria (76%), burning micturition (40%), retention of urine (28%) and haematuria in 16% cases.

In Prostate carcinoma, all of the patients had complaints of sensation of incomplete emptying of urinary bladder, weak urinary stream and hesitancy (100%) followed by frequency and nocturia (96%), intermittency and urgency (92%), dysuria (88%), burning micturition (76%), haematuria (20%) and retention of urine in 16% cases.

AUA score of patients of BPH and CA-prostate are shown in Table 2 and Table 3.

Other associated symptoms in cases of BPH/Prostate carcinoma are given in Table 4.

Blood Urea and Serum Creatinine levels of the patients were as per Table 5 and Table 6 respectively.

In BPH, 84% cases were vegetarians and 48% were smokers and 12% were alcoholics.

In Prostate carcinoma, 72% cases were vegetarians, 64% were smokers and 28% were alcoholics.

Findings of DRE were as per Table 7.

Findings of cystoscopy were as per Table 8.

USG findings of the patients were as per Table 9.

X-ray KUB findings in cases of BPH and CA-prostate patients is as per Table 10.

X-ray KUB finding in BPH patients were normal KUB in most of the cases of BPH i.e., 23 cases (92%). In only 2 cases i.e., 8% cases, there was left ureteric stone present.

X-ray KUB finding in Prostate carcinoma patients- normal KUB was found in most of the Prostate carcinoma cases i.e., 84% (21 cases). There was left ureteric stone in 4% cases and left renal stone in 4% cases. In 8% cases, osteoblastic secondaries were seen in iliac bone.

Serum PSA level, in BPH patients was found to be normal in 10 cases i.e. 40% and was found to be between 5-10 ng/mL in 15 cases i.e. 60%. Serum PSA level, in Prostate carcinoma patients was found to be between 21-40 ng/mL in 8 cases i.e. 32%. Serum PSA level was found to be between 5-20 ng/mL in 6 cases i.e. 24%; was found to be between 41-60 ng/mL in 5 cases i.e. 20%; was found to be between 81-100 ng/mL in 3 cases i.e. 12%; was found to be > 100 ng/mL in 2 cases i.e. 8% and between 61-80 ng/mL in 1 case i.e. 4%. (Table 11).

Serum TSH level in all the BPH patients was found to be within normal limits. It was found to be between 1.0-3.0 µIU/mL in 24 cases i.e. 96% and was found to be between 0.3 to 0.9 µIU/mL in 1 case i.e. 4%. (Table 12).

Serum TSH level in Prostate carcinoma patients: it was found to be within normal limits in most of the cases. It was found to be between 1.0-3.0 µIU/mL in 22 cases i.e. 88% and was found to be between 0.3 to 0.9 µIU/mL in 1 case i.e., 4%. It was found to be increased i.e. >5.0 µIU/mL in only 2 cases (8%) and serum PSA level was >100 ng/mL. (Table 12). These two cases were associated with osteoblastic secondaries in iliac bone and histopathologically was found to be high-grade tumour with Gleason score 8.

In CA prostate patients, histopathological findings showed well-differentiated tumour in 17 cases (68%), intermediate-grade tumour in 6 cases (24%) and high-grade tumour in 2 cases (8%). (Table 13).

Gleason score, in Prostate carcinoma patients was found to be between 2 to 4 in 17 cases (68%) and to be between 5 to 7 in 6 cases (24%) and between 8 to 10 in 2 cases (8%). (Table 14).

Sl. No.	Age (years)	BPH		Ca-Prostate	
		No. of Cases	Percent	No. of Cases	Percent
1.	< 50	1	4	Nil	0
2.	51 – 60	7	28	3	12
3.	61 – 70	7	28	13	52
4.	71 – 80	9	36	6	24
5.	> 80	1	4	3	12

Table 1. Distribution of Patients According to their Age Groups

Findings of DRE were as per Table 7.

Prostate cancer spread has predictable patterns, known to affect the prostatic contours. Of the asymmetrical contours, 55 (34%) were caused by cancer, and of the cancer foci, 55 (20%) generated asymmetrical contours.[9]

One of the physical sign of a malignant prostate is asymmetry of gland. The finding of a patient with a relatively early prostate cancer is suggested by a firm nodule in one of the prostate lobes. As it enlarges, it may occupy the whole of one lobe and/or extend posteriorly to invade one or both of the seminal vesicles, giving extension shaped like horns of a bull. The central sulcus may be distorted or lost altogether and the rectal mucosa may become fixed to the gland. As the disease becomes more extensive, it may also invade both prostatic lobes and be felt as a hard, irregular, nodular structure with extensions of tumour laterally to the pelvic walls and these fixed the position of gland within the pelvis.

Bone survey films (skeletal radiography) are insensitive as a method to screen for the presence of bone metastasis. Lentle and co-workers (1974) demonstrated that 50% of the bone density must be replaced by tumour before standard radiographic imaging method identifies distant spread. Skeletal radiography is recommended only for confirmation of a positive bone scan in men in whom bony metastasis are not suspected at initial evaluation.[10]

Many of the men presenting with prostate cancer may have metastasis at time of diagnosis, the commonest site for these being in the bones. The lumbar spine is often affected and deposits of metastatic tissue may invade or compress the spinal cord and give rise to lower limb neurological signs. Other physical signs that may be associated with a diagnosis of advanced prostate cancer include a hydronephrotic kidney due to unilateral or bilateral ureteric obstruction and signs of renal impairment.

As general guidelines, the majority of men (70-80%) with PSA values less than 4.0 ng/mL have pathologically organ-confined disease, more than 50% of men with PSA levels greater than 10.0 ng/mL already have established capsular penetration and more men (75%) with serum PSA levels greater than 50 ng/mL have positive pelvic lymph node.[11]

Although the overall positive predictive value of the DRE was poor, most patients diagnosed with prostate cancer had an abnormality on the DRE that corresponded either to the location of cancer detected on biopsy or had cancer volumes on prostatectomy specimens large enough to be palpable. Higher serum PSA levels even if less than 4.0 ng/mL were associated with dramatic increases in prostate cancer detection.[12]

High serum TSH levels in men with Gleason 8 prostate cancer is a result of the elaboration of TSH by cancer cells. Bone mineral density in the face of normal levels of thyroid hormone depends on an intact response to TSH, which ordinarily suppresses both osteoblast and osteoclast differentiation, thereby exerting control over bone remodelling. However, with abnormally high TSH levels this process may become deranged, promoting the development of bone metastases. If TSH production by prostate cancer cells could be suppressed, the incidence of bone metastases might be reduced.[13]

In a study by Sawin CT et al, done in 344 relatively healthy persons older than 60 years, 22 (5-9%) had a clearly elevated level of serum thyrotropin (TSH) (greater than 10 μIU/mL), a finding more common in women than in men. A further 14.4% had a slightly elevated level of serum TSH (> 5 and ≤ 10 μIU/mL). The study did not find any correlation between elevated serum TSH and prostatic malignancy.[13]

In a prospective study, Phadke MA et al estimated serum prolactin, TSH, LH, FSH and inhibin level using radioimmunoassay, in normal subjects and in patients with benign prostatic hyperplasia (BPH), before and after tumour resection. In cases of benign prostatic hyperplasia, no significant changes in the level of TSH were noted after surgery.[14]

In another prospective study by Salminen et al (2004), levels of serum thyroid stimulating hormones (TSH), free thyroxine (fT_4) and thyroid binding globulin concentrations were measured in prostate cancer patients treated with either radiotherapy and androgen deprivation for 12 months (AD) or radical radiotherapy alone. The study concluded that prolonged use of AD hampers the interpretation of thyroid test results by causing a significant decline in fT_4 at 6 and 12 months.[15]

A study by Frokovic et al (1994) reported development of TSH-secreting small cell prostate cancer (SCPC) from high-grade adenocarcinoma (Gleason score 8) with an elevated number of chromogranin A positive cells located in benign structures adjacent to the cancer. Conversion to SCPC was followed up during 4 years. The study concluded (i) extremely poor prognosis associated with high grade adenocarcinomas that demonstrate stronger immunohistochemical positivity for prostatic acid phosphatase (PAP) than for PSA, (ii) chromogranin A positive cells in benign structures adjacent to the cancer as a possible paracrine promoter of SCPC from poorly differentiated adenocarcinoma.[16]

In yet another study, Aprikian et al (1994) attempted to determine the correlation of neuroendocrine differentiation and deoxyribonucleic acid content in lymph node and skeletal metastasis. They immunohistochemically examined 62 metastatic lesions (41 pelvic lymph nodes and 21 bone metastases) for the presence of chromogranin-A expressing tumour cells. Of 41 lymph nodes and 21 bone metastases, 19 (46%) and 11 (52%) respectively contained chromogranin-A immunoreactive cells. Peptide hormone immunocytochemistry in 19 cases (12 lymph nodes and 7 bone metastases) demonstrated neuroendocrine cells containing TSH in 17 (89%) cases.[17]

Abbreviations

TSH – Thyroid Stimulating Hormone
PSA – Prostate Specific Antigen
BPH – Benign Prostatic Hyperplasia
CA Prostate – Prostate carcinoma
DRE – Digital Rectal Examination
TURP – Trans-urethral Resection of Prostate
EDA – Exploratory data analysis
AUA – American Urology Association
X-ray KUB – X-ray of Kidney, Ureter and Bladder Region.

CONCLUSION

Serum PSA level in most of the BPH patients was found to be within normal limits and serum TSH level in all of the BPH patients was found to be within normal limits.

Serum PSA level in all the Prostate carcinoma patients was found to be increased and it was found to be >100 ng/mL in only 8% cases of Prostate carcinoma. Serum TSH level in most of the Prostate carcinoma patients was found to be within normal limits and it was found to be increased only in 8% cases of Prostate carcinoma. Histopathology in Prostate carcinoma patients was found to be well differentiated with tumour with Gleason score 2 to 4 in 68% cases followed by intermediate-grade tumour with Gleason score 5 to 6 in 24% cases followed by high-grade tumour with Gleason score 8 in only 8% cases and in these 8% cases there was associated skeletal metastases (osteoblastic secondaries in iliac bone).

By this study, it is hereby concluded that only in 8% cases of Prostate carcinoma, patients had very high PSA level (>100 ng/mL) as well as increased serum TSH level and these cases were associated with Gleason score 8 (high-grade tumour) and skeletal metastases.

Further statistical/epidemiological studies are required for confirmation of these findings.

ABSTRACT

BACKGROUND

Gastroesophageal reflux disease, alkali or acid ingestion, achalasia due to unknown aetiology are considered as main causative factors in the genesis of benign oesophageal strictures. The two types of treatment modalities are used including conservative dilatation and surgical approach according to aetiology and site of involvement. Our study attempts to understand the various aetiopathogenesis and epidemiological features of this problem and their clinical presentation; so that early detection maybe planned and various treatment modalities for achalasia cardia, peptic stricture, corrosive stricture and their results are evaluated.
The aim of the study is to study various-

1. Aetiological factors of stricture oesophagus (benign).
2. Features and clinical presentation of stricture oesophagus, so that early detection maybe planned.
3. Treatment methods of management of benign oesophageal strictures.

MATERIALS AND METHODS

This is a descriptive study of dysphagia due to benign oesophageal strictures. Cases presenting in the surgical outdoor with symptoms suggestive of oesophageal stricture and admitted in different surgical and gastroenterology units were included in the study. A detailed history and examination was done in these patients. Management was done by endoscopic or manual dilatation with bougies and/or surgical operation. Surgical management consisted of Heller's cardiomyotomy or oesophagoplasty.

RESULTS

Total number of 40 patients of dysphagia due to benign oesophageal strictures were studied out of which 16 (40%) patients were of corrosive strictures, 14 (35%) having achalasia cardia and 10 (25%) of peptic strictures. The male-to-female ratio was 1.35:1. The mean age was 42.62 years. Strictures due to corrosive were more common in younger age groups while 20170912mthe peptic stricture occurred later in life. The incidence of various symptoms were dysphagia 100%, regurgitation 45%, epigastric or substernal pain 35%, weight loss 25% and cough in 12% cases. Patients with GERD or achalasia cardia had more dysphagia to liquid/semi-solids, while patients with corrosive ingestion (alkali/acid) had more dysphagia to solids. The most common site affected was lower third of oesophagus in 55% of cases, followed by middle third (40%) and upper third (5%). In present study, out of 40 patients, 25 patients were treated conservatively in form of dilatation and operative intervention was done in 15 patients. All of the patients of stricture due to GERD were treated by conservative management. Most of the patients with corrosive ingestion/unknown aetiology were treated by conservative management. All of the patients with achalasia cardia were treated by operative management. One patient out of 25 managed with conservative treatment developed complication in the form of oesophageal perforation. Out of 15 patients that were managed by operative treatment, 5 developed pulmonary complications and 5 developed wound infections. Out of 4 patients who had undergone oesophagoplasty, 2 suffered with minor anastomotic leaks. In our study, after treatment (surgery/dilatation), 85% of patients were able to swallow most of solids and liquids, 10% of patients could swallow only solids and 5% of patients could swallow only liquids or semisolids.

CONCLUSION

It can be concluded that dysphagia due to benign oesophageal stricture maybe because of post-corrosive stricture, peptic stricture, achalasia cardia, etc. Conservative treatment in the form of dilatation gives excellent results in management of dysphagia. The surgery should be offered to the patients who are otherwise fit and dilatation cannot be done due to very narrow stricture. In operative patients, results of Heller's cardiomyotomy and esophagoplasties are excellent.

BACKGROUND

Oesophagus is "the organ about which so little is known" and even today unfortunately, the oesophagus remains a no man's land, into whose top end, the ENT surgeons make light reconnaissance's and whose bottom end is often attacked by abdominal surgeons under cover of the diaphragm.

Physicians (from their greater elevation) still like to drop consignments of antacids down it, but these do not alter its abnormal configuration.

Other causes include aggressive treatments for Barrett oesophagus (such as photodynamic therapy) and nasogastric tube injury.[2]

Out of 40 patients of benign dysphagia, 23 (57.50%) patients were male and rest 17 (42.50%) were female. The male-to-female ratio was 1.35:1 (Table 1).

In the present series, most of patients were between 15-45 years, i.e. 62% of patients. The youngest patient of benign dysphagia (corrosive) was 18 years and oldest was of 80 years. The mean age was 42.62 years (Table 2).

69% of corrosive stricture patients were under the age of 30 years and 60% of peptic stricture patients were between 61-75 years (Table 2).

In present series, most of patients were between 15-45 years, i.e. 62% of patients. The youngest patient of benign dysphagia (corrosive) was 18 years and oldest was of 80 years. Strictures due to corrosive were more common in younger age groups while the peptic stricture occurred later in life. It may be due to more incidence of either accidental or suicidal ingestion of corrosive in younger age group with early development of stricture post ingestion. Peptic strictures develop in later age after longstanding peptic disease.

The median age of patients of dysphagia due to benign oesophageal lesions as reported by various authors was-

Median age of corrosive patients were 40 years (range 8-80 years) and 35.7 years (range 15-68 years) in study by Huang MH[3] (1989) and Stoica AL[4] (2004), respectively. In a study by Arevalo Silva C[5] (2006), a biphasic distribution of the patients was noted, half were children under 5 years old and the remainder were adults more than 35 years. The most frequent cause for ingestion was accidental (67%) as opposed to attempt suicide (33%). All cases of attempted suicide occurred in adults. Most of them reported ingestion of large amounts of caustic substance.

Median age of achalasia patients were 36.5 ± 14.6 years, 44 years, 44.5 ± 14 years (range 16-76), 41.42 ± 18.07 years and 40 years in Ghoshal[6] (2004), Harold KL[7] (2004), Onopriev VI[8] (2005), Boztas G[9] (2005) and Kennedy (2010)[10], respectively.

In peptic stricture, patients were of 61.1 ± 16.3 years and 56.1 years (range 32-82 years) in Mazzadi SA[11] (2004) and Chiu YC[12] (2004), respectively.

In the present study, 25% of patients had history of GERD, but in Said A[13] (2003) study, the incidence was 77 (Table 3).

In the present study, 15 (37%) cases had history of alkali ingestion. This was similar to that of Huang MH[3] (1989) and Arevalo Silva C[5] (2006) who reported the incidence of 38% and 42%, respectively (Table 3).

In our study, acid ingestion induced strictures were 2.5% while in study by Arevalo Silva C[5] (2006), it was 32% (Table 3).

Unknown aetiology and achalasia were presented in 35% of cases in our study (Table 3).

Patti MG[14] (2005) reported 77% of achalasia cases and Arevalo Silva C[5] (2006) reported 32% of acid ingestion, which produce benign dysphagia.

This variation in aetiological factors and age maybe due to difference in cultural and dietary habits in Indians from other countries.

Initially, sign and symptoms due to benign oesophageal stricture are minimal and nonspecific for a long duration. Often patients do not seek medical advice until the appearance of clear-cut symptoms of dysphagia and/or regurgitation appear (Table 4).

The first and the most important symptom was progressive dysphagia, which was present in 100% of cases in our study. Unfortunately, dysphagia is not an earlier manifestation of the disease, because it manifests only after reduction of 60% of oesophageal luminal diameter occurs.

Functional Grading of Dysphagia[15]

Grade I- Eating normally.
Grade II- Requires liquids with meal.
Grade III- Able to take semisolids, but unable to take any solid food.
Grade IV- Able to take liquid only.
Grade V- Unable to take liquid, but able to swallow saliva.
Grade VI- Unable to swallow saliva.

The incidence of various symptoms were dysphagia 100%, regurgitation 45%, epigastric or substernal pain 35%, weight loss 25% and cough in 12% cases, which are comparable with study of Mazzadi SA[11] (2004) in which dysphagia (100%), regurgitation (40%) and epigastric pain (30%). Similar results were found in study of Ghoshal UC[6] (2004) with dysphagia (100%), regurgitation (48%), epigastric pain (17%), weight loss (26%) and pulmonary symptoms occurred in 18% cases.

One significant observation that emerged from this study was that 50% of patients presented with dysphagia for liquids or semi solids, 35% were only for solid and remaining 15% patients were having dysphagia for both solids and liquids. Patients with GERD or achalasia cardia had more dysphagia to liquid/semi-solids, while patients with corrosive ingestion (alkali/acid) had more dysphagia to solids (Table 5).

The relationship between symptoms and severity of injury is uncertain. Stridor and drooling were considered 100% specific for significant oesophageal injury, but no single symptom or symptom cluster can predict the degree of oesophageal damage.[16]

In present series, majority of patients, i.e. 40% presented with <3 months' duration followed by 30% with 3-6 months' dysphagia, 15% with 6-9 months' dysphagia and only 5% of patients presented after 1 year of dysphagia.

Barium swallow reports were available for 30 patients. Oesophageal lesion with stricture and hold up of contrast with proximal dilatation were present in 55% patients, in 20% patients, the barium swallow was normal, which were later on proved to have the oesophageal stricture on endoscopy. Remaining 10 patients had peptic strictures and this investigation was not called for (Table 6).

In the present study, the most common site affected was lower third of oesophagus, in 55% of cases, followed by middle third (40%) and upper third (5%) (Table 7).

Dascalescu C[17] (2005) reported that corrosive poisons produced the lesion in 62% cases in oesophagus followed by 26% at oesophagogastric junction. The study of Mazzadi SA[11] (2004) on peptic stricture shows 97% of stricture present in lower one third of oesophagus.

Chiu YC et al (2013) reported that, of the 18 patients with oesophageal stricture alone, 6 had orifices of strictures located in the upper third of the oesophagus, 6 in the middle third and 6 in the lower third.[18]

Tharavej C et al (2017) reported that, 8 out of 55 patients (14.5%) had perforations.[28]

In their study, Hsieh KH et al (2017) reported that 1 oesophageal perforation developed after balloon dilatation (1/63).[27]

Aghaji MA[32] (1993) reported that major postoperative complications were proximal anastomotic leaks 49%, wound sepsis 25%, pulmonary complications 27% and colon graft necrosis 4% of cases.

In our study, after treatment (surgery/dilatation), 85% of patients were able to swallow most of solids and liquids, 10% of patients could swallow only solids and 5% of patients could swallow only liquids or semisolids (Table 14).

In our study, 60% of patients were discharged within 3 days of admission (which were treated conservatively), 90% discharged within 9 days of admission. Only 10% patients were discharged after 9 or more days, which suffered from wound infections or other operative complications.

CONCLUSION

It can be concluded that dysphagia due to benign oesophageal stricture maybe because of post-corrosive stricture, peptic stricture, achalasia cardia, etc. Conservative treatment in the form of dilatation gives excellent results in management of dysphagia. The surgery should be offered to the patients who are otherwise fit and dilatation cannot be done due to very narrow stricture. In operative patients, results of Heller's cardiomyotomy and esophagoplasties are excellent.

Abstract: It is known that breast cancer is most common cancer in women of developed countries and is on rise in developing countries. Besides recurrence, one of the major complications is lymphoedema. This study was done on women who presented with lymphoedema after primary surgical treatment of breast cancer. A detail history was recorded with special emphasis on irradiation to axilla, chemotherapy and hormonal therapy. They were specifically asked regarding the mode of onset of lymphoedema. A detailed physical examination was done with special emphasis on diagnosis of lymphoedema. The data were then analyzed based on Exploratory Data Analysis. Out of 1047 patients who underwent surgical intervention, the occurrence of lymphoedema is 6.017% with maximum occurrence in age group 56-65 years (8.3%) with maximumoccurrence of lymphoedema observed in 2nd year after primary surgical treatment. Maximum occurrence of lymphoedema was observed in T2 subgroup (8.15%), N1 subgroup (7.33%), and in MRM subgroup (6.67%). Patients who were irradiated after surgery showed higher occurrence of lymphoedema (13.64%). Maximum occurrence of lymphoedema was seen within 1-2-year post mastectomy (47.62%) and in patient with T2, N1 stage. There was consistent increase in occurrence of lymphoedema with increase in BMI & patient with history of radiation post mastectomy.

INTRODUCTION

Breast cancer is the most common cancer in women of developed countries and is on rise in developing countries [1]. Besides recurrence, one of the major complications is lymphoedema.

Lymphoedema can cause severe physical and psychological morbidity in breast cancer survivors and measurable reduction in quality of life in respect to functional, emotional, physical and social wellbeing. Studies have shown that women who develop lymphoedema exhibit higher levels of psychological, social, sexual and functional morbidity than those who do not develop this complication. Keeping this in mind I would like to throw some light on this clinical entity.

It is not a new topic of consideration for practitioners and researchers concerned with skin and wound care. In 1587, the noted Ming Dynasty Physician Gong Tingxian described 'phlegm-damp'accumulation and treatment. More recently King and DiFalco [2] discussed the rise of lymphoedema in an ageing population. They highlighted the array of skin problems associated with lymphoedema and noted that such conditions lead to cellulitis which further damages the lymphatic system. They state that "... most lymphoedema is the result of surgical treatment of malignant disease. Because malignancy is increasingly curable, the latent potential for developing lymphoedema is growing medical problem."

Lymphoedema following breast cancer treatment is traditionally attributed to lymphatic obstruction with venous obstruction as an infrequent complicating factor. The lymphatic system also known as 'Third Circulation' consists of thin walled, low pressure vessels, nodes that occur along the course of lymphatic vessels. By regulating fluid absorption from the interstitium, the lymphatic system maintains plasma drainage routes by surgery, radiotherapy, and disturbances in Starling forces in the skin and

Table-5: Distribution of all post-surgical patients and patients with lymphoedema according to Radiotherapy

Radiotherapy	Total Post-Surgical Patients	Patients with Lymphoedema	Lymphoedema Occurrence
Yes	242	33	13.64%
No	805	30	3.72%
Total	1047	63	6.017%

Table-6: Distribution of all postsurgical patients and patients with lymphoedema according to Body Mass Index

BMI	Total Post-Surgical Patients	Patients with Lymphoedema	Lymphoedema Occurrence
<25	501	23	4.59%
25-30	483	31	6.42%
>30	63	9	17.46%
Total	1047	63	6.017%

duration of lymphoedema, Body Mass Index, mastectomy, and past history of cellulitis [13], though obesity is not directly related to breast cancer [14]. Helyer L K et al. (San Francisco) performed a study on "obesity a risk factor developing post-operative lymphoedema". The study of BMI by multivariate analysis revealed that patients with BMI >30 had an odd ratio of 2.93 with those of BMI <25 of having lymphedema [15]. Edward TL reported that body weight or BMI are important factor that increase the risk of lymphedema [16]. In present study there was consistent trend of increase in occurrence of lymphoedema with increase in BMI, in subgroups of <25, 25-30, >30.

Edwards found that the number of lymph nodes removed was not correlated with lymphoedema[16]. Roses et al. stated that the number of removed lymph nodes was not a risk factor in multivariate analysis, but in univariate analysis it increased the risk [17]. In present series patients were assigned into three categories with respect to number of lymph nodes removed i.e. <15, 15-25, and >25. Out of 63 patients 42 patients (66.07%) belong to the group where the number of removed lymph nodes were between 16-25, 19 patients (30.16%) rest in group where number of removed lymph nodes were <15.

Nikanen's study supports an increase in incidence of edema in patients irradiated post operatively [11]. A study conducted by Schuemann (San Diego, US) showed the highest incidence of edema was among patients who had received radiotherapy in high doses with few fractions to the axilla (60%) [18]. Radiologyinfo.org reviewed that radiation therapy given to the axillary lymph nodes can increase the risk of patients developing arm swelling ("lymphoedema") following axillary (armpit) dissection [19].

In present study occurrence of lymphoedema was higher in the patients who were irradiated (13.64%) as compared to those who didn't receive radiotherapy (3.72%). Out of 63 patients who developed lymphoedema, 33 patients were given postoperative radiotherapy.

CONCLUSION

- The occurrence of lymphoedema in patients registered in breast clinic was found to be 6.017%.
- Maximum occurrence of lymphoedema was seen within 1-2 years i.e. 47.62% after primary surgical treatment followed by 23.80% seen between 2-3 years. Then there was decrease in occurrence of lymphoedema with increase in duration after surgery.
- Patients, who received radiotherapy where axillary dissection was performed, had increased risk of lymphoedema (13.64%).
- 53.96% of patients having lymphoedema were having tumor size ranging from 2-5 cm with overall incidence of 8.15%.
- 57.14% of patients having lymphoedema were node positive, with maximum incidence of lymphoedema.
- There was consistent increase in occurrence of lymphoedema with increase in BMI. The occurrence of lymphoedema was 4.59%, 6.42% and 17.46% in BMI categories < 25, 25-30 and > 30 respectively.

ABSTRACT

Background: Lymphoedema is one of the most undesirable complication that is anticipated in patients of cancer breast post mastectomy. A comprehensive care of patient of lymphoedema is required which includes, prevention, early diagnosis and treatment. In the study conducted, efficacy of non-operative management of lymphoedema is observed.
Methods: A descriptive study was conducted on women who presented with lymphoedema post-mastectomy. Thirty-three patients were studied for non-operative management. Treatment of patients was carried out with physiotherapy, massage, compression bandages and stockings and Intermittent pneumatic compression by pneumatic compression pump.
Results: Patients were categorized according to the grades, duration of lymphoedema, type of treatment they received and effect of the treatment.
Conclusions: Lymphoedema being dreaded complication, much attention needs to be given on its prevention post mastectomy. But in country like India, compliance and regular follow up is not possible for every patient, especially for the patients of the rural background. The same pattern of dearth in compliance follows in management of lymphoedema. Non-operative management is an effective mode of treatment in cases of post-mastectomy lymphoedema.

Keywords: Lymphoedema, Non-operative management, Post-mastectomy

INTRODUCTION

Lymphoedema is one of the most undesirable complication that is anticipated in patients of cancer breast post mastectomy. Carcinoma breast being common disease and a great deal of improvement in management of patients lead us to give more emphasis on quality of life and long-term post treatment sequalae.

There is expectation on the part of patient, their family, and care givers that the patient should lead a near normal life. Lymphoedema being chronic debilitating disease results in significant swelling of limb, disfiguring body image and may lead to functional disability. So postmastectomy upper limb lymphoedema may be said to be the paradigm for discussion of follow up care.

Clinically, lymphoedema results from abnormal accumulation of protein in the interstitial space causing interruption of normal lymphatic drainage channels. Initial swelling is due to excess fluid collections in subcutaneous tissue resulting in pitting oedema. This is the initial fluid phase of lymphoedema. Longstanding lymphoedema leads to chronic accumulation of inflammatory fluid with fibrocyte and adipocyte resulting in deposition of fats in subcutaneous tissue with resultant non-pitting oedema. This is known as solid phase of lymphoedema.[1,2] Axillary lymph node dissection may further alter the lymph node transfer capacity.

lymphoedema after mastectomy (Table 2). Distribution of patients according to the severity of lymphoedema (Table 3).

Low grade lymphoedema responded to physiotherapy and massage; moderate grade lymphoedema needed compression bandage and/or pneumatic compression; severe grade lymphoedema needed all the four modalities. Distribution of patients according to the treatment they received (Table 4). Mode of treatment according to the severity of lymphoedema (Table 5).

Two thirds of the patients who received physiotherapy and massage only responded well with reduction in lymphoedema. Moderate grade lymphoedema responded well (76.4%) to physiotherapy and massage along with compression bandage. Moderate to severe grade lymphoedema also needed intermittent pneumatic compression and responded well to these modalities (83.3%). Most of the patients with various grades of lymphoedema responded well to non-conservative treatment with reduction in their lymphoedema. Efficacy of non-operative treatment in patients of lymphoedema (Table 6).

Table 6: Efficacy of treatment in patients of lymphoedema.

Treatment given	No. of patients	Reduction	Static	Progression
PT+Msg	33	22(66.6%)	7(21.1%)	4(12.1%)
PT+ Msg+ CB	17	13(76.4%)	3(17.6%)	1(5.8%)
PT+ Msg+ CB + IPC	6	5(83.3%)	1(16.6%)	0

DISCUSSION

Lymphoedema being dreaded complication, much attention needs to be given on its prevention post mastectomy. But in country like India, compliance and regular follow up is not possible for every patient, especially for the patients of the rural background. The same pattern of dearth in compliance follows in management of lymphoedema.

In the study done, patients were subjected to non-operative management which includes; physiotherapy and massage, compression bandages and intermittent pneumatic compressions.

These treatment methods were studied based on their synergistic effectiveness on lymphoedema.

Kuno et al, (US) made an investigation of lymphoedema and function of the arm in 1,115 patients after mastectomy. Slight edema was present in 26.7%, moderate lymphoedema was observed in 3.9% and severe in 0.9%.[5]

Lymphoedema was dependent on extensiveness of surgical operation. Three stages of lymphoedema have been described in CMAJ 2001. Stage 1 presents with pitting and is considered as reversible; stage II presents brawny, fibrotic, non-pitting and is irreversible; stage III presents as advanced lymphoedema in which cartilaginous hardening occurs with papillomatous outgrowths and hyperkeratosis of skin.[6,7]

In present study 31 patients (prevalence=2.96%) were of grade I lymphoedema, 14 patients (prevalence=2.87%) belongs to category of grade II lymphoedema, 2 patients had grade III lymphoedema.

Dennis (US) reported only 9 patients but observed a large variability in the time between surgery and onset of lymphoedema i.e. between 2 months and 3 years.[8]

In present series maximum number of patients i.e. 30 patients (47.62%) developed lymphoedema between 1 to 2 years after surgery followed by 15 patients (23.81%) who developed lymphoedema between 2-3 years.

In present study patients were categorized according to grades of lymphoedema. Out of 33 patients who were treated for lymphoedema, 17 patients had mild lymphoedema. Moderate lymphoedema was present in 14 patients and severe lymphoedema was seen in 2 patients.

Johansson et al (US) examined the effects of low stretch compression bandaging (CB) or in combination with manual lymph drainage (MLD) in 38 female patients with arm lymphoedema after treatment for breast cancer. After CB therapy for 2 weeks, the patients were allocated to either CB or CB +MLD for 1 week. Arm volume and subjective assessment of pain, heaviness, and tension were measured. The mean volume of reduction for total group during part I was 26% and during part II in CB+MLD group was 11% and in CB group it was 4% which was significantly different($p=0.04$).[9]

In present series MLD was offered to 17 the patients of mild lymphoedema along with regular physiotherapy. There was considerable reduction in arm swelling along with relief in pain and heaviness in 9 patients. There was mild reduction or swelling remained static in 4 patients. Progression of disease was seen in 2 patients who were inconsistent with treatment. Two patients with mild lymphoedema were lost to follow up.

There were 9 patients of moderate lymphoedema who were offered compression bandages and stockings along with massage and physiotherapy. There was reduction in

ABSTRACT

BACKGROUND

The incidence of vascular trauma has increased considerably during the past 40 years. Although, they represent less than 3% of all injuries, they deserve special attention because of complications and limb loss.

MATERIALS AND METHODS

This was a descriptive study. Over a period of one year, 98 patients were operated for peripheral vascular injuries. Physical examination was used for diagnosis with the use of duplex ultrasonography/ CT angiography where needed. Vascular repair was carried out in terms of primary repair or interposition vein graft and fasciotomy was considered as and when required. Patients with non-salvageable extremity requiring primary amputation were excluded from the study.

RESULTS

Most of the patients were male. Most common cause was road traffic accidents. Occurrence of concomitant orthopaedic injuries was very high in this study. The commonly injured artery was popliteal artery (38.7%) and brachial artery (27.5%). Surgical procedures performed were interposition vein grafts in 54% cases, whereas end-to-end repair in 20.4% cases. The limb salvage rate was 76.53%.

CONCLUSION

Early diagnosis and treatment of vascular injury is important for limb salvage. Patients should be surgically intervened even after golden period has passed, because with limb or without limb matters a lot.

HOW TO CITE THIS ARTICLE: Verma H, Sain RS, Sethi D, et al. Peripheral vascular trauma- a limb may be saved. J. Evolution Med. Dent. Sci. 2018;7(14):1732-1736, DOI: 10.14260/jemds/2018/391

BACKGROUND

Vascular trauma is a fast growing emergency for vascular surgeons. The incidence of vascular trauma has increased considerably during the past 40 years. Vascular injuries comprise of 3% of all civilian traumas and continue to have significant associated morbidity and mortality in the 21st century.[1] Although, they represent only 3% of all injuries, they deserve special attention because of complications and limb loss.

Various common mechanism of injury seems to differ in different parts of the world[2,4] and include blunt and penetrating trauma, stab wound, gunshot wound and RTA with later being the most common cause in majority of cases.[4] In view of urgent need of intervention, usually physical examination is used for diagnosis with the use of duplex ultrasonography/ CT angiography where critically indicated. CTA provides accurate and timely diagnosis of peripheral vascular injuries and challenges the gold standard of arteriogram.[5]

In the past attempts to control arterial bleeding were by means of cauterisation method, manual compression and pouring boiling liquid materials on the wounds. Ambroise Pare initially used the ligation method during XVI century.[4] While first and second world wars gave knowledge of diagnosis and treatment of vascular injuries, vascular reconstructive methods were mainly introduced during the Korean and Vietnamese wars with a tremendous progress[3,4] and a dramatic decrease in amputation rate.[2,3,6,7] Successful treatment of major arterial injuries is life-saving and allows limb salvage with restoration of function[6]; however, return of function also depends on concomitant nerve injury.[7]

Vascular trauma is associated with major morbidity and mortality, but little is known about its incidence or nature in our region. This study was done in 98 patients who underwent operative intervention for vascular trauma. This report presents the different mechanisms of vascular trauma, arteries involved, associated bone or nerve injuries and types of vascular intervention done and specially limb salvage rate at our centre. Injury to major peripheral artery causes limb ischaemia and if not repaired at proper time then can lead to loss of limb. That is why vascular trauma should be dealt within 6 hrs. of injury, which is called as golden period. But at our centre most of the patients present after passing of these golden hours because of delay in diagnosis or transportation. Still we moved on to repair these limb-threatening arterial injuries and got good limb saving results. We excluded crushed injuries, badly infected wound, limb with gangrenous changes and injuries presented after 100 hrs.

due to delayed presentation and infection (1), while 1 case underwent toes amputation. Overall limb salvage rate was 76.53%.

DISCUSSION

Despite modern surgical interventions, vascular injuries can still cause extremity loss and even death. According to some authors, amputation rates can even reach 78%.[8] In our study amputation rate was 23%, while it was 6%,[9,10] 7.7%,[11] 14.6%[7] and 17.24%[12] in other studies. The extremity salvage in our study was 76.53%, while it was 84%,[7,9,11] 94%[10] and 95%[13] in others. Cause of less percentage of limb salvage may be due to delayed presentation.

Successful outcome in vascular trauma depends on early diagnosis and intervention. In our set-up, majority of the patients presented beyond what is considered as the "Golden Period."

In this study Road traffic injury was the commonest cause (60%), mainly in male patients. This may be due to population and road discrepancy. Also women usually do not prefer driving in our region. Vascular injuries are frequent among young male population,[7,9,10,14] and in this study male patients composed of 93% of the cases with lower limb involvement (60.20%), more common than upper limb (39.79%).

Vessels, nerves and bones may be injured together due to their close relation anatomically.[15,16]

In our study, popliteal artery was the most commonly injured artery (37.75%) followed by brachial artery (26.53%).

Bone fractures and nerve lesions in this study involved 65% and 12% of cases respectively. The patients with bone fracture, nerve injury and severe soft tissue injuries were assessed by related disciplines and appropriate intervention was done. In our patients with fractures external fixation was more preferred because of easier application and low infection risk.

Peripheral angiography in vascular injuries is controversial. Some authors are suggesting angiography to every pre-operative patient.[8,17,18,19] Many clinicians report their successful vascular injury results without angiography.[7,14,20,21] We followed only clinical diagnostic method for early intervention and peripheral angiography was only done in cases with multilevel vascular and orthopaedic injuries. In all the patients with associated orthopaedic injuries, the orthopaedic surgeon performed reduction and fixation of fracture and/ or dislocation prior to the vascular repair. In one study, end-to-end repair was done in 26.75%, vein graft in 21%, PTFE graft in 1.9% and ligation in 8.9% cases.[7]

Reversed saphenous vein interposition graft in this study was used most commonly to repair the artery (53%) with end-to-end repair done in 20% cases and PTFE graft was used in 3% cases, while in another study primary repair in 55.5% cases and vein graft 35.2% cases.[10] Ligation was done in 6 cases.

ABSTRACT

Background: Diagnostic laparoscopy has been in the armamentarium of the surgeon and gynaecologist for many years as a useful technique for evaluating pelvic pathology and it is now one of the most frequently performed laparoscopic procedures. The purpose of this study is to evaluate the role of diagnostic laparoscopy in undiagnosed pain abdomen. The Objectives of this study is to evaluate laparoscopy as a diagnostic tool in cases of undiagnosed abdominal pain where clinical symptoms and investigations are not conclusive and to evaluate benefits and complications of diagnostic laparoscopy.

Methods: The study was done in 60 patients, presenting with chronic undiagnosed pain abdomen to a tertiary care hospital. All the patients were operated under general anesthesia in supine position. Diagnostic laparoscopy was done using 3 ports, one umbilical 10 mm, other two depending upon possible pathology. After the study, the data was analyzed to evaluate the role of laparoscopy in undiagnosed abdominal pain.

Results: Out of 60 patients, 44 were female and 16 males. On diagnostic laparoscopy, findings were- chronic appendicitis - 31, chronic appendicitis with left ovarian cyst - 1, endometriosis with adhesions - 3, PID - 5, PID with adhesions - 3, suspected TB (GI/Genital) - 4, adhesions - 12, negative diagnostic lap - 1. So it may be concluded that diagnostic laparoscopy is a very useful tool to establish diagnosis in patients with undiagnosed abdominal pain with the following benefits are, superior diagnostic ability, better visualization of the abdominal cavity including the paracolic gutters and the pelvis, able to pin point the sites of adhesions with adhesiolysis during the same procedure, retrieval of specimen for histopathological examination, management of the pathology during the same procedure, avoiding unnecessary laparotomy, low complication rate.

Conclusions: Laparoscopy is an efficient tool in the armamentarium of the surgeon to diagnose the patients of undiagnosed pain abdomen with numerous benefits and minimal complications.

Keywords: Adhesiolysis, Diagnostic, Laparoscopy, Laparoscopic appendicectomy, Undiagnosed pain abdomen

INTRODUCTION

The term laparoscopy has been derived from a Greek word 'lapara' which means 'body wall' or 'flank' and 'skopein' which means 'to examine'. The terms 'laparoscopy' and 'peritoneoscopy' are interchangeable, however, peritoneoscopy is the preferred term as the purpose is to examine the contents of peritoneal cavity and not the abdominal wall.[1]

Chronic abdominal conditions represent a major group of cases for a general surgeon. In the majority of cases, diagnosis can be made by clinical examination and sometimes with the help of basic and advanced

RESULTS

A total of 60 patients with undiagnosed abdominal pain underwent diagnostic laparoscopy after thorough clinical examination and a battery of selected laboratory tests. Imaging techniques like X-ray and abdominal ultrasound were helpful in some but not in all the cases.

The procedure was evaluated as a positive outcome when one of the following were seen or done.

- Positive pathologic findings correlated with clinical and ultrasound examination.
- Positive pathologic findings not correlated with clinical and ultrasound examination or a new diagnosis was established.
- Therapeutic procedure done to relieve the obvious pathology encountered inside the abdominal cavity.

However, in certain instances, conversion to laparotomy was done, when the surgery was not proceeding further as desired.

Age and sex wise distribution of patients

Out of 60 cases, the maximum number of patients 31.6% was in the age group between 31-35 years, followed by age group 21-25 years and 26-30 years (Figure1). Female patients outnumbered the male patients by a ratio of 44:16 (Figure2).

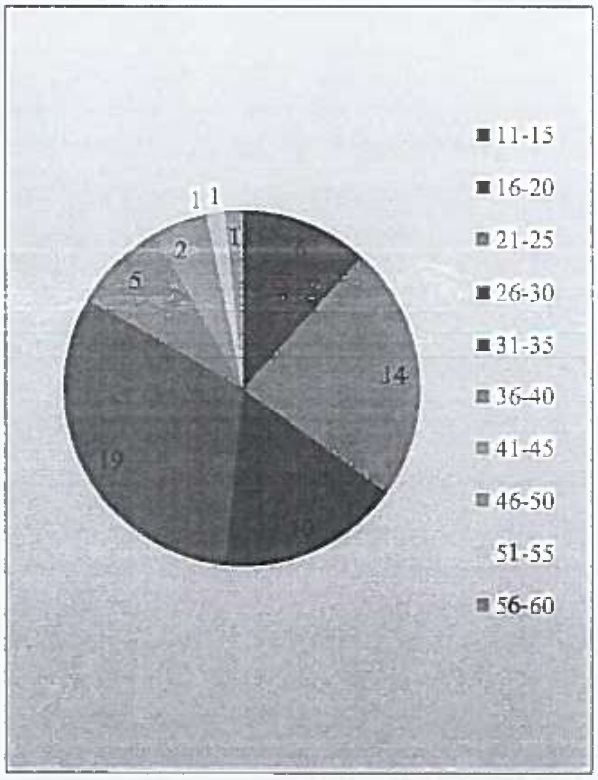

Figure1: Age wise distribution of patients.

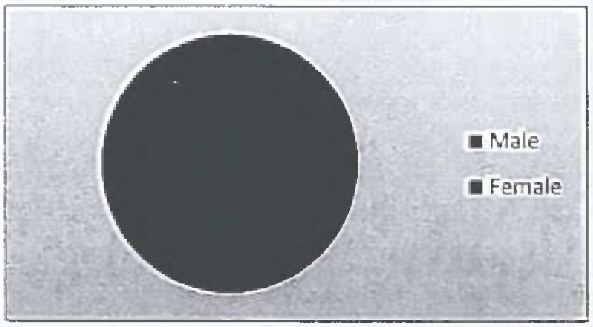

Figure 2: Sex wise distribution of patients.

Site

Most common primary site of occurrence of pain/tenderness in the abdomen was the right iliac fossa (60%), followed by around the umbilicus in 20% and the hypogastrium in 15%. Sites such as epigastrium and right hypochondrium were present in remaining 5%.

Bar

Associated complaints

The most common associated complaint was vomiting in 9 patients, followed by Diarrhoea and constipation 6, Dysuria 4, Abdominal Distention 3 and Discharge Per Vaginum 3.

Past surgical history (Other than normal vaginal delivery)

The most common significant past history was of abdominal sterilization that was present in 6 out 44 female patients (14%), followed by 9 cases each of LSCS and TAH/SOO. Out of 44 females, 27 patients had no significant past history. Male patients had no significant past history (Table 1).

Table 1: Previous medical or surgical history in females.

Past history	No. of cases	% (out of 44)
Sterilization (Abdominal tubal ligation)	6	14
LSCS	4	9
TAH/ SOO	4	9
Tuberculosis	3	7
Insignificant	27	61
Total	44	100

Ultrasonography

In most of the cases (47) USG was normal study. Six patients showed chronic Appendicitis in their USG. In 3 patients, USG showed small Renal calculi, but site of their pain was not corresponding to their USG findings.

DISCUSSION

In surgical practice pain in the abdomen is a frequent complaint in both the sexes and may present as an acute or chronic condition. A patient with abdominal pain, acute or chronic, almost always poses a diagnostic challenge for a surgeon. Hospitalizing the patient and performing frequent examinations when they present with atypical signs employ a "wait-and-watch" approach while some are scheduled for elective or emergency exploratory laparotomy. Diagnostic laparoscopy is a worthy alternative to laparotomy which may be even more informative than former with the added advantage of performing multiple therapeutic procedures.

Diagnostic laparoscopy is a minimally invasive surgical procedure that allows the visual examination of intra-abdominal organs in order to detect pathology.

Diagnostic laparoscopy has been embraced by the surgeon for the diagnosis of a wide range of abdominal diseases and the application of laparoscopic technique for the treatment of many of these diseases have accelerated its use as a diagnostic tool. In the present study, the average age was 30.83 years (range 11-59 years) which was comparable with the other study by Al-Bareeq et al having average age 31 years (16-62 years).[6] The sex ratio in present study was Female: Male 2.75:1 which was comparable to that of Easter et al and Lavonius et al.[7,8]

The primary site of pain/tenderness in present study was right iliac fossa (60%) followed by umbilicus (20%) and hypogastrium (15%) which was comparable to the series of the study conducted by Klingensmith et al who reported the reproducible tenderness to be close to 50%.[9]

History of previous surgery

A history of previous surgery was present in 23% of the cases in the present study (all patients were female). The history of previous surgery should be a relative contraindication to laparoscopic examination and that laparoscopy in patients with multiple previous abdominal operations is not entirely safe.

With the advent of open technique for creation of pneumoperitoneum this no longer holds true.[9,10] Diagnostic laparoscopy should be performed in patients who have chronic abdominal pain, especially if they have had previous surgery or pelvic inflammatory disease because a laparotomy causes formation of newer adhesions while laparoscopy is associated with a low frequency of post-operative adhesion formation.[8]

Findings in diagnostic laparoscopy

In the present study, the most common finding based on gross morphology during laparoscopy was appendicitis (chronic) seen in 32 patients (53.3%), followed by PID in 8 cases. In study by Onders et al, appendicular pathology was found in only 16% cases while in study by Al-Bareeq et al, it was 73%.[11,6]

Intra peritoneal adhesions were present in 18 cases (30%) while in the study of Arya et al, it was in 8% cases only. Adhesions are common source of pain especially in the patients who have undergone some elective abdominal procedure in the past.

One of the major benefits of diagnostic laparoscopy is that we can, not only accurately pin point sites of adhesions but also perform adhesiolysis in the same operative session thus relieving the patient of adhesion induced pain in a majority of circumstances.[12] Diagnostic laparoscopy facilitates the retrieval of histopathologic specimen without sacrificing on the patient comfort and cosmetic issues.

In the present series, the final outcome based on histopathology ha not deviated much for the gross diagnoses made during surgery mainly due to the panoramic view, brilliant illumination and extensive examination of the abdominal cavity done during diagnostic laparoscopy.

Establishment of accurate diagnosis by laparoscopy in chronic abdominal pain

Establishment of accurate diagnosis was achieved in 98.3%of the cases in our study. In previous years, diagnostic accuracy by laparoscopy was only 47% while in the current years diagnostic accuracy has raised to 99 - 100%.[7,6,11,13] Hence it may be considered a useful tool in the diagnosis of undiagnosed pain abdomen.

Laparotomy avoided

In our study using laparoscopy 58 cases (96.6%) were saved from undergoing laparotomy, similar results were observed by Schrenk et al (94%) and Onders et al (100%).[14,11]

Complications of diagnostic laparoscopy

In our study, minor complications were observed in 1 case (1.6%). In other studies, also, complication rate was found to be quite low as in the study by Udwadia (0.09%).[15]

The low incidence of complications during laparoscopy can be explained on the basis of the availability of better instruments, for example, the use of Hasson's cannula for creation of pneumoperitoneum by open technique in patients with previous history of abdominal surgery, and due to availability of a better expertise and training to the laparoscopic surgeon.[16]

So, it may be concluded that diagnostic laparoscopy is a very useful tool to establish diagnosis in patients with undiagnosed abdominal pain with the following benefits:

ABSTRACT

Background: Perforation of bowel, particularly ileal perforation, is a significant emergency surgical problem in developing and underdeveloped nations and usually associated with high morbidity and mortality. The study is focussed on evaluating the impact of protective ileostomy in ileal perforation and to compare its outcome in term of post operative complication, hospital stay, psychological impact and mortality with primary surgery without ileostomy and observe its effect on prognosis of patient as a whole. Aim of the study we compared two modalities of treatment, primary surgery without ileostomy v/s primary surgery with protective defunctioning ileostomy with respect to post operative complications, duration of hospital stay, morbidity, mortality and psychological impact.

Methods: We studied 50 patients of ileal perforation (diagnosed per-operatively) admitted to tertiary level hospital and operated upon for laparotomy. Patients were divided in 2 groups: Group A = Protective defunctioning ileostomy along with primary surgery, and Group B = Primary surgery alone. Primary surgery includes primary closure of perforation or resection and end to end anastomosis.

Results: The commonest cause of non-traumatic ileal perforation was typhoid (52%) followed by non specific, tuberculosis and diverticulitis. Different types of operative procedures were performed. In Group A, total no. of dreaded complications like faecal fistula was 1 while in Group B, 10 patients developed faecal fistula. Other complications like wound infection and wound dehiscence were 28% in Group A while 96% in Group B. Overall mortality rate was 24% with 12% mortality in group A and 36% in group B. Mean hospital stay in Group A patient was 12.640±5.75 days (1-23 days) and those of group B was 23.760±16.04 days (5-59 days).

Conclusions: Construction of protective defunctioning ileostomy in case of distal ileal perforation repair or anastomosis greatly reduces the dreaded complication and mortality in comparison to perforation repair or anastomosis without protective ileostomy. Although it is associated with ileostomy related complications, but they are only temporary and obviously no more than the price of life saved.

Keywords: Defunctioning ileostomy, Faecal fistula, Ileal perforation, Protective ileostomy

INTRODUCTION

Perforation of bowel, particularly ileal perforation, is a significant emergency surgical problem in developing and underdeveloped nations and usually associated with high morbidity and mortality. Most common cause of ileal perforation is typhoid; other may be tuberculosis, trauma and non specific enteritis. Patients usually present with abdominal pain and tenderness with signs of peritonitis like abdominal guarding and rigidity etc. Late cases may present with severe toxic state. Surgical intervention is the definite treatment for it. Various

There was male preponderance in this study with male to female ratio of 3.5:1 (Table 2).

Most of patient presented with symptoms and signs of peritonitis. The commonest symptoms were pain abdomen, fever, vomiting. The common sign were abdominal tenderness, guarding and rigidity, absent bowel sounds, abdominal distension and obliteration of liver dullness. Gas under right dome of diaphragm was found in 89% of the patients.

Table 1: Age incidence.

Age (years)	Number of cases	Percentage (%)
≤20	5	10
21-30	14	28
31-40	13	26
41-50	8	16
51-60	5	10
61-70	5	10
Total	50	100

Table 2: Sex incidence.

	Group A		Group B		Total	
Sex	No. of cases	%	No. of cases	%	No. of cases	%
Male	19	76	20	80	39	78
Female	6	24	5	20	11	22
Total	25	100	25	100	50	100

The commonest cause of non-traumatic ileal perforation was typhoid (52%) followed by non specific, tuberculosis and diverticulitis. Widal was done in all patients in whom ileal perforation was diagnosed per-operatively. Widal test for typhoid was positive in 52% of patients. Histopathological evidence of typhoid found in 7 cases out of 26 cases of typhoid. Diagnosis of tuberculosis was made in 5 cases and diverticulitis in one case. Rest of cases showed features of non specific inflammation with no definitive aetiology (Table 3).

Table 3: Aetiology of Ileal Perforation.

Diagnosis	Total cases	Percentage (%)
Typhoid	26	52
Non-specific	18	36
Tuberculosis	5	10
Diverticulitis	1	2
Total	50	100

During laparotomy feculent peritonitis was seen in 44% of cases and purulent peritonitis on 56% cases. 74% of patient had single perforation, 16% had two perforations and 10% have three or more perforations. 74% patient had associated ileitis adjacent to perforation, only 26% had healthy bowel.

Different types of operative procedures were performed. Out of 25 patients in Group A; in 19 cases, primary closure of perforation(s) with proximal loop ileostomy and in 6 cases, resection anastomosis of ileum with proximal loop ileostomy was done. Out of 25 patients in Group B; in 20 cases, primary closure of perforation(s) and in 5 cases, resection anastomosis of ileum was done (Table 4).

Table 4: Operative procedures.

Group A		Group B	
Procedure	Number	Procedure	Number
Primary closure of perforation(s) with proximal loop ileostomy	19	Primary closure of perforation(s)	20
Resection anastomosis of ileum with proximal loop ileostomy	6	Resection anastomosis of ileum	5
Total	25	Total	25

Post operative complications were encountered in varying proportions in both groups. Faecal fistula was most dreaded fatal complication. In Group A, total no. of dreaded complications like faecal fistula was 1 while in Group B, 10 patients developed faecal fistula. Other complications like wound infection and wound dehiscence were 28% in Group A while 96% in Group B. In Group A, Ileostomy related complications like Skin excoriation, Ileostomy prolapse, Ileostomy retraction, etc. were also present. Overall mortality rate was 24% with 12% mortality in group A and 36% in group B (Table 5).

Table 5: Post-operative complications (n=25) in each group.

Complications	Group A		Group B	
	No. of patients	%	No. of patients	%
Wound Infection	5	20	14	56
Wound Dehiscence	2	8	10	40
Skin Excoriation	18	72	0	0
Ileostomy Prolapse	1	4	0	0
Ileostomy Retraction	5	20	0	0
Electrolyte Imbalance	4	16	1	4
Faecal Fistula	1	4	10	40
Psychological Symptoms	7	28	8	32
Death	3	12	9	36

certainly better when a protective defunctioning Ileostomy is formed to protect the distal anastomosis or perforation closure. Ileostomy specific complications however increase the post-op morbidity. These complications can be reduced, if not out-right eliminated, by proper fashioning of stoma. It is of paramount importance that ileostomies are properly sited and constructed. A stoma should be formed by surgeon who is not only technically skilled but also understands the potential metabolic and mechanical problems associated with ileostomy. Morbidity, mortality and thus, the economic burden was significantly high in group B patients.

Protective ileostomy greatly reduced the occurrence of faecal fistula in patients there by reducing the mortality, although was associated with stoma related complication. Though bothersome, ileostomy is still a life saving and damage control surgical procedure. It should be recommended that ileostomy in these cases is only temporary and extra cost of management is not more than price of life saved.

Table 6: Outcome of study (n=25) in each group.

Complications	Group A	Group B	P value	Statistical significance
Hospital stay (days)	12.64	23.76	0.000	Highly significant
Wound infection	20%	56%	0.009	Significant
Wound dehiscence	8%	40%	0.008	Significant
Skin excoriation	72%	0	0.000	-
Ileostomy prolapse	4%	0	0.312	-
Ileostomy retraction	20%	0	0.018	-
Electrolyte imbalance	16%	4%	0.157	Insignificant
Faecal fistula	4%	40%	0.002	Significant
Psychological symptoms	28%	32%	0.758	Insignificant
Death	12%	36%	0.040	Significant

CONCLUSION

Construction of protective defunctioning ileostomy in case of distal ileal perforation repair or anastomosis greatly reduces the dreaded complication and mortality in comparison to perforation repair or anastomosis without protective ileostomy. Although it is associated with ileostomy related complications, but they are only temporary and obviously no more than the price of life saved. However, further controlled trials may be needed for more details on the matter.

ACKNOWLEDGEMENTS

Authors would like to thanks Pratap Bhan Kaushik, Statistician and Deepak Soni for valuble support during study.

DOI: https://doi.org/10.33545/surgery.2019.v3.i4g.278

Abstract
Introduction: Breast cancer is the most common of the types of cancer occurring in India, followed by lung cancer and cervical cancer. Breast cancer is categorized into operable and advanced breast cancer for the management purpose. While early detection is the key for successful breast cancer treatment, one in three women in rural India had not even heard of the deadly disease. Due to lack of awareness most of women from rural background reach hospitals with advanced disease. This study was done to determine how different modalities of treatment affect the outcome in advanced breast cancer patients with rural background.
Aims and Objectives: To evaluate cases of advanced breast cancer clinically and by relevant investigations in rural population. To evaluate the role of surgery either in the first presentation of patient or after chemotherapy.
Materials and Methods: This study was conducted in Rabindranath Tagore Medical College, Udaipur (Rajasthan). A total of 40 patients with locally advanced breast cancer were evaluated.
Conclusion: In the patients of locally advanced carcinoma breast with rural background, surgery with adjuvant chemotherapy is a better option in comparison to neoadjuvant chemotherapy followed by surgery. The reason is that many of patients do not return for surgery after neoadjuvant chemotherapy.

Keywords: breast cancer, locally advanced breast cancer, rural background, modified radical mastectomy

1. Introduction

Breast cancer is the most common of the types of cancer occurring in India, followed by lung cancer and cervical cancer. Breast is the most commonly diagnosed cancer among women in the Western world accounting for 1/5th (18%) of all cancers in women. Every year about one million women and several thousand men are diagnosed with breast cancer worldwide and approximately 60,000 die from it (Parkin DM *et al.* 2005) [1]. Breast cancer is the most common site specific cancer in women and a leading cause of death due to cancer between 40-45 years of age (Sethi A Sethi D 2015) [2]. In India, it is the most common cancer in females with 75,000 new cases occurring every year as per the cancer registries in the country in urban females. Breast cancer is categorized into operable and advanced breast cancer for the management purpose. Advanced breast cancer is either locally advanced or metastatic disease. Locally advanced breast cancer (LABC) is characterized by varying clinical presentations such as presence of a large primary tumour (>5 cm), associated with or without skin or chest-wall involvement or with fixed (matted) axillary lymph nodes or with disease spread to the ipsilateral internal mammary or supraclavicular nodes in the absence of any evidence of distant metastases (Valero V 1996) [3]. These cancers are classified as stage IIB, IIIA, IIIB or IV breast cancer according to the American Joint Committee for Cancer Staging and End Results Reporting (5th Ed. 1997) [4]. Locally advanced breast cancer is a very common clinical scenario especially in developing countries (30-60%) possibly due to various factors like lack of education and poor socio-economic status. With this wide spectrum of presentation, management of LABC is a challenge for the surgeon. Treatment of LABC has evolved from single modality treatment, consisting of radical mutilating surgery or higher doses of radiotherapy in inoperable disease to multimodality management consisting of surgery, radiation therapy (RT), chemotherapy with or without hormonal therapy and others.

While early detection is the key for successful breast cancer treatment, one in three women in rural India had not even heard of the deadly disease. Due to lack of awareness most of women

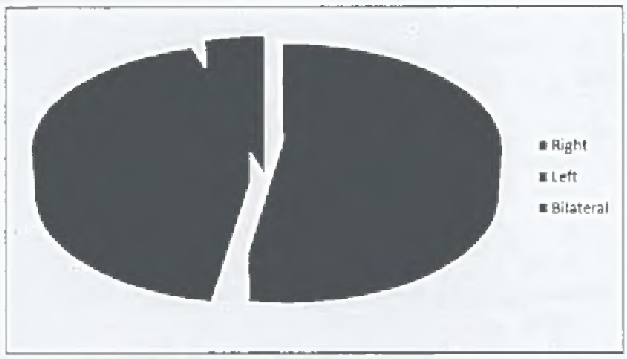

Fig 4: Distribution of breast cancer patients according to side involvement (n=40)

Figure 4 shows that 52.5% cases had right side breast involvement only while 42.5% had left side involvement only and 2 cases (5%) were having involvement of both breasts.

Table 1: Distribution of cases according to location of tumour (quadrant) (n=40)

S. No.	Location	No. of patients	Percentage
1.	Upper outer quadrant	13	32.5
2.	Upper inner quadrant	4	10.0
3.	Lower outer quadrant	2	5.0
4.	Lower inner quadrant	1	2.5
5.	Central	2	5.0
6.	More than one quadrant	18	45.0

Table 1 show that maximum cases (45%) had tumour localized in more than one quadrant, 32.5% presented with tumour in upper outer quadrant, 10% in upper inner quadrant and 5% in lower outer quadrant and 2.5% cases had in lower inner quadrant.

Table 2: Family history of cancer among breast cancer cases (n=40)

S.No.	Family history of cancer	No. of patients	Percentage
1.	Family h/o breast cancer	2	5.0
2.	Family h/o other cancer	4	10.0
3.	No family h/o cancer	34	85.0
	Total	40	100

Table 2 shows that 15% patients of breast cancer had family history of cancer. Out of these, only 5% had family history of breast cancer and 10% had cancer other than breast.

Table 3: Distribution of cases according to tumour size (based on TNM staging) (n=40)

S. No.	TNM staging	No. of patients	Percentage
1.	T_X	-	-
2.	T_1	-	-
3.	T_2	-	-
4.	T_3	34	85.0
5.	T_4	6	15.0
	Total	40	100

Table 3 shows that majority of patients (85%) presented in stage T3 and 15% in stage T4.

Table 4: Distribution of breast cancer cases according to lymph nodes status (clinical assessment based on TNM staging) (n=40)

S. No.	Lymph node status	No. of patients	Percentage
1.	N_0	-	-
2.	N_1	33	82.5
3.	N_2	6	15.0
4.	N_3	1	2.5
	Total	40	100

Table 4 show that 33 patients (82.5%) presented with N_1 stage node involvement while one case (2.5%) had N_3 involvement and in 6 patients (15%) had N_2 involvement.

Table 5: Distribution of breast cancer cases according to histopathological types and their grading (n=40)

S. No.	Histopathological type	No. of patients	%	Grade I		Grade II		Grade III	
				No.	%	No.	%	No.	%
1.	Ductal carcinoma	33	82.5	25	75.75	5	15.15	3	9.09
2.	Medullary carcinoma	6	15.0	5	83.33	1	16.67	-	-
3.	Lobular carcinoma	1	2.5	1	100	-	-	-	-
	Total	40	100	31	77.5	6	15.0	3	7.5

Table 5 shows in infiltrating ductal carcinoma (75.75%) cases were grade I and 15.15% cases were grade II and only 9.09% were grade III. In medullary carcinoma 83.33% were grade I and 16.67% were grade II. In lobular carcinoma, only 1 one case (100%) was grade I. Overall grade I, II and III were 77.5%, 15.0% and 7.5%, respectively.

Table 6: Distribution of breast cancer cases according to metastasic status in follow up (n=40)

S. No.	Metastasis	No. of patients	Percentage
1.	Metastasis developed during follow up	4	10
2.	No metastasis during follow up	32	80
3.	Lost in follow up	4	10
	Total	40	100

Table 6 shows that 4 patient (10%) developed metastasis during follow up and no metastasis is seen in rest of patients.

Table 7: Status of the patients at the time of presentation in breast cancer patients

S. No.	Patients presenting with	No. of patients	Percentage
1.	Locoregional recurrence	3	7.5
2.	Presenting first time to hospital	37	92.5
	Total	40	100

Table 7 shows that 3 patients (7.5%) who were operated elsewhere presented to us with locoregional recurrence. The remaining cases presented first time to the hospital.

background, surgery with adjuvant chemotherapy is a better option in comparison to neoadjuvant chemotherapy followed by surgery. The reason is that many of patients do not return for surgery after neoadjuvant chemotherapy.

Abstract

Introduction: Vascular injuries of extremities are a very important cause of morbidity and mortality in the society. The incidence of vascular trauma has increased considerably during the past few decades.

Materials and Methods: This study was conducted at a tertiary level hospital over a period of 6 years. A total number of 690 patients presented with extremity vascular trauma that underwent the operative procedure. Patients with isolated venous trauma, unsalvageable extremity injury requiring primary amputation, trauma with severe multiple system involvement, and patients presenting more than 100 h after injury were excluded from the study. This study was done to evaluate the mode and type of injuries, arteries involved and methods to re-establish vascular continuity, and end result of the vascular intervention.

Results: Six hundred ninety patients, including 660 (95.6%) men and 30 (4.3%) women, were operated. Most of the patients (55.4%) were between 20 and 40 years old. The most common cause of vascular injury was road traffic accidents (93%). The most common artery involved was popliteal artery and contusion was the most common pattern of injury. Interposition vein graft was the most common mode of repair. Over all limb salvage rate was 79%.

Conclusion: Vascular injury to extremity requires prompt recognition and referral to a vascular center. Immediate revascularization has excellent results and less morbidity.

Key words: Arterial repair, Road traffic accident, Save limb, Vascular injury to limb, Vascular trauma to extremity

INTRODUCTION

Vascular injuries of extremities are a very important cause of morbidity and mortality in the society. The incidence of vascular trauma has increased considerably during the past few decades. The great majority of these injuries are due to road traffic accidents (RTA), penetrating trauma with sharp objects, and gunshot wounds.[1] Despite modern surgical interventions, vascular injuries can still cause extremity loss and even death.[2] Timely intervention to re-establish vascular supply to the affected limb is very crucial; otherwise, it may result into limb loss or mortality due to bleeding, ischemia, renal failure, and secondary complications like – infection. Vascular reconstruction leads to a dramatic decrease in amputation rate.[3] Successful treatment of major arterial injuries may be lifesaving as well as allowing limb salvage and restoration of function.[4] Return of function is often related to the presence of concomitant injury to peripheral nerves and bones.[5]

Our center is a tertiary care center and largest hospital of state. It drains nearby states also. Although delay occurs because of transportation or diagnostic delay, still our aim is to provide vascular continuity as early as possible with simultaneous treatment for nerves, bones, and other injuries.

This retrospective study was done in 690 patients who underwent an operative procedure for vascular trauma in the past 6 years to evaluate the mode and type of injuries, arteries involved and methods to re-establish vascular continuity, and end result of the vascular intervention.

MATERIALS AND METHODS

This retrospective observational analytic study was conducted at our center Sawai ManSingh Medical College,

Corresponding Author: Dr. Hemlata Verma, Department of Surgery, Sawai Man Singh Medical College, Jaipur - 302 004, Rajasthan, India.

most common vascular injury in upper extremity was brachial artery injury in 169 patients (24.5%) followed by ulnar/radial artery injury in 66 (9.6%) cases. In the lower extremity, the popliteal artery was the most frequently affected artery as it was injured in 276 (40%) cases followed by femoral artery in 141 (20.4%) cases [Table 5].

Vascular injury was more often associated with orthopedic injuries, as both occurred in 528 patients, mostly in the form of fracture or dislocation. The concomitant vein or nerve injury occurred in 85 patients [Table 6]. The arterial repair was performed after orthopedic intervention for bone injuries.

Contusion was the most common pattern of arterial injury (51.9%) followed by complete transection (31.3%) [Table 7].

The most common mode of repair was by use of reversed saphenous vein interposition graft to repair the artery (52%) followed by end-to-end repair in 30% cases. Ligation (anterior or posterior tibial artery) was done in 2.4% cases. No intervention was done in 10 cases because after exposing the artery, pulsations were present with no visible vascular injury. This may be due to angulation of artery by corner of fractured or dislocated bone which relieved after manipulation [Table 8].

In the upper extremity, the most common type of reconstruction was end to end anastomosis followed by inter-position vein grafting while in lower extremity it was inter-position vein grafting followed by an end to end anastomosis. A balloon embolectomy catheter was used to remove thrombus and to confirm the patency of the artery proximally and distally.

Table 5: Artery involved

Artery	No. of cases	Percentage
Subclavian	2	0.3
Axillary	12	1.7
Brachial	169	24.5
Radial/ulnar	66	9.6
Femoral	141	20.4
Popliteal	276	40.0
Anterior tibial/posterior tibial	24	3.5
Total	690	100

Table 6: Associated injury

Injury	No. of cases	Percentage
Bone	528	76.5
Major nerve injury	27	3.9
Major vein injury	58	8.4

A repair of major venous injury was performed in 58 cases. Nerve repair was done in 27 cases. Fasciotomy was performed in 110 patients, mostly (103 cases) in the lower extremities and only in seven cases in the upper extremity.

In spite of the presentation after 6 h, the results of the repair were extremely good. Of 138 patients who presented within 6 h, 130 achieved warm limb with a palpable distal pulse. In 552 cases of delayed presentation, we were able to save limb in 427 cases. In 125 cases of vascular repair, limb remained cold, mainly in patients who presented after 24 h [Table 9].

Post-operative complications in the form of infection were seen in 61 (8.8%) cases, secondary hemorrhage in 20 (2.9%). A total of 145 (21%) patients end up with amputation of limb (125 due to cold limb postoperatively and 20 due to infection or secondary bleeding). A total of 13 patients (1.9%) expired [Table 10].

Overall limb salvage rate was 79%.

The mean duration of hospitalization was 10 ± 5 days (range 5–30 days). The duration of hospitalization was significantly longer in lower extremity injuries compared to upper extremity injuries.

Table 7: Pattern of arterial injury

Injury	No. of cases	Percentage
Contusion	358	51.9
Spasm/angulation	25	3.6
Partial transection	69	10.0
Complete transection	216	31.3
Multiple site	22	3.2
Total	690	100

Table 8: Type of arterial repair/operation

Repair	No. of cases	Percentage
Embolectomy only	10	1.4
Lateral sutures	74	10.7
End to end repair	207	30
Vein graft	359	52
PTFE graft	13	1.88
Ligation	17	2.4
No intervention	10	1.5
Total	690	100

Table 9: Result of vascular repair/operation

Presentation	Total number	Warm limb and pulse, both present	Warm limb only, no pulse	Cold limb
Early (within 6 h)	138	130	8	0
Late (after 6 h)	552	232	195	125
Total	690	362	203	125

exploration, proximal and distal arterial control must be established before a repair is attempted; and vascular reconstruction is preferable to ligation.

A well-stabilized skeleton is essential before definitive arterial repair.[27] However, Hunt and Kingsley suggested that arterial revascularization should be followed by skeleton stabilization and nerve and tendon repair.[28] In this study, skeleton fixation was done before vascular repair.

In arterial injuries, successful results were obtained in arterial reconstruction procedures, which were held within 6–8 h after the event. Almost all of the amputations performed in our study were late cases that were revascularized after 8 h of injury. Infection is also a major factor, which increases the amputation rate after a successful vascular surgery. For this reason, vigorous and appropriate tissue debridement is important before and after the revascularization procedure.[29] In our study, 61 (8.84%) patients developed infection, which was treated with good antibiotic coverage, debridement of wound, and regular dressing of the wound. Of 61 infected cases we were able to save limb in 48 patients and amputation was done in 13 cases.

This study is limited by its retrospective nature and by reflecting experience at one tertiary center only. Further studies are warranted to confirm the hypotheses raised by the observations described.

CONCLUSION

The vascular injury requires prompt recognition and referral to a vascular center. Early diagnosis and immediate treatment of vascular injury are necessary to reduce morbidity and mortality. Patients should be surgically intervened even after the golden period has passed because with a limb or without limb matters a lot.
